## Foreword to Version 2.1

This report is a revised and extended version of the report from Althaus et al. (2004) on the datasets of the version 1.1. It comprises

- corrections of reported errors,
- extension of inventories by new metals and the related updating of established inventories and
- some restructuring in the report structure.

The changes to version 1.2 and 1.3 as documented in Frischknecht et al. (2006) are integrated entirely where it concerned the datasets contained in this report.

The extension of the metals database consists of primary Cadmium, primary Indium, Gold and Silver (both primary and secondary as well as supply mix), Lead (secondary and supply mix), Tantalum (capacitor powder) and the metals Gallium, Arsenic and Tellurium as semiconductors.

Since most of these metals are by-products from the Zinc / Lead cycle, a new Part has been created that hosts the respective content from the original Part VIII Other Metals in Althaus et al. (2004) which in turn has been suspended. Its remaining contents have been reallocated: The copper alloys brass, bronze and brazing solders to Part II Copper; Magnesium and Tin to new individual parts.

The original inventories as they were established in version 1.1 through 1.3 are not altered. No general changes were made to actualise dated information such as supply and use patterns. Further the discussion of selected LCI / LCIA results has not been updated with the v2.0 calculation results. The respective chapters have been deleted.

The Overview on the following page provides a schematic representation of the changes of this report as compared to the report on data v1.1 in Althaus et al. (2004).

Compared to version 2.0, the version 2.1 contains a new part on antimony and several corrections and updates.

## Part I

# Aluminium

Data v2.1 (2009)

Author: Hans-Jörg Althaus, EMPA, Dübendorf

Review Roland Hirschler, EMPA, St. Gallen

Classen M., Althaus H.-J., Blaser S., Tuchscheid M., Jungbluth N., Doka G., Faist Emmenegger M. and Scharnhorst W. (2009) Life Cycle Inventories of Metals. Final report ecoinvent data v2.1, No 10. EMPA Dübendorf, Swiss Centre for Life Cycle Inventories, Dübendorf, CH, Online-Version under: [www.ecoinvent.ch](http://www.ecoinvent.ch).

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1

## Acknowledgement

We thank Bernard de Gélas and Christian Leroy of the European Aluminium Association (EAA) for providing the unit process data of their study and for their help with the interpretation of the data. We also thank Eirik Nordheim of the EAA and Gerald Reblizer of Alcan Technology & Management for their valuable comments to the report and the data.

## Comments on this version 2.1

This part corresponds to the original report in Althaus et al. (2004) that has been updated with the changes reported in Frischknecht et al. (2006), where the factor for resource consumption in the bauxite mining was corrected. Beside this change the CO emission in the dataset “aluminium, primary, liquid, at plant” (RER) which was inventoried as “biogenic” in earlier versions was corrected to “fossil”.

Chapter “6 Cumulative Results and Interpretation” of the original report has not been adapted and was deleted for this report.

Note that the flow names in the tables displaying unit processes have not been updated to reflect the name changes with version 2.0. This namely affects the designation of transportation service flows.

## Summary

The aluminium production is modelled for the European situation, primarily based on data from the European Aluminium Association (EAA (2000) and personal communications. The mining represents a world-wide situation primarily based on Mori & Adelhardt (1998).

Some of the datasets described in this report make only sense in the context of the aluminium production and are therefore not intended for other uses. Intermediate products like aluminium hydroxide and aluminium oxide however can be used to represent these chemicals in other applications.

The datasets to be chosen to represent aluminium in a LCA study are either the primary aluminium (chapter 5.3), one of the secondary aluminium datasets (chapter 5.4) or one of the production mixes (chapter 5.5). The decision whether to use primary, secondary or a mix of the two depends on the goal and scope of the LCA to be conducted.

# 1 Introduction

This part deals with primary and secondary aluminium production. Because bauxite, aluminium hydrate and aluminium oxide are mainly consumed in the aluminium production, these chemicals are also included in this report.

A considerable part of the aluminium consumed today is secondary material. Thus also the collection of aluminium scrap and the recycling process are included.

A simplified overview of the processes is given in Fig. 1.1.

Fig. 1.1 Simplified overview of the processes for the aluminium production

## 2 Reserves and Resources of Materials

Aluminium is the most important light metal in the outer earth crust. It never occurs in nature in its metal form but only in compounds with other elements. Bauxite, the main resource for the aluminium production, is used to 85% for this purpose (Mori & Adelhardt (1998)).

Bauxite, the mineral from which aluminium oxide is gained, is mined mainly in the regions north and south of the tropical rainforests and most of the aluminium oxide is produced close to the mining sites (Tab. 2.1). The yearly bauxite mine production was 71 Mt/a in 1983 and the estimated reserves are 22.5 Gt (Hudson et al. (1997)). The yearly bauxite consumption rose to 140 Mt/a in 2002<sup>1</sup>.

**Tab. 2.1 World wide bauxite and aluminium oxide production (Mori & Adelhardt (1998), p. 20)**

|                                       | Aus-<br>tralia | Guinea | Ja-<br>maica | Brasil | China | Vene-<br>zuela | India | Russia | USA | Europe |
|---------------------------------------|----------------|--------|--------------|--------|-------|----------------|-------|--------|-----|--------|
| % of world bauxite production         | 38             | 13     | 10           | 9      | 6     | 5              | 5     | 3      |     |        |
| % of world aluminium oxide production | 30             |        | 7            |        | 5     |                |       | 6      | 30  | 10     |

98% of the industrial production of aluminium is done by electrolysis of aluminium oxide (Hall-Heroult process). This process requires a big amount of electricity. Thus most of the aluminium smelters are located in areas with cheap electricity be it from coal, nuclear or from hydro power plants. The electricity used to produce aluminium for the European market is produced according to Tab. 2.2 (EAA (2000)).

**Tab. 2.2 Electricity distributed by energy source for the production of primary aluminium for the European market**

| Energy re-<br>source | brown coal | hard coal | natural<br>gas | crude oil | nuclear<br>electricity | hydro<br>electricity |
|----------------------|------------|-----------|----------------|-----------|------------------------|----------------------|
| Share [%]            | 5.1        | 20        | 4.6            | 3.1       | 14.6                   | 52.6                 |

Because of the high energy input needed in primary aluminium production, secondary aluminium is an important resource. The overall share of secondary aluminium on the world aluminium market is estimated to be 32%<sup>2</sup> by industrial experts<sup>3</sup>.

<sup>1</sup> Eirik Nordheim, European Aluminium Association. Personal communication, 15.04.2004

<sup>2</sup> This figure is so low because the aluminium market is growing. The share of aluminium that is recycled after use is very variable depending on the application (e.g. in the building sector in Europe between 92% and 98%).

<sup>3</sup> Dr. G. Rombach, Project manager Recycling, Hydro Aluminium Deutschland GmbH. Personal communication, 1.10.2002 <http://www.aluminium.org/statistics/overview.asp>, accessed 18.12.2002

## 3 Characterisation of the materials

### 3.1 Bauxite

The term bauxite [CAS Nr. 1318-16-7] is used for sedimentary rocks that contain economically recoverable quantities of the aluminium minerals gibbsite, boehmite, and diaspore. The average crude ore that is mined contains 47.9% bauxite. The world average aluminium oxide content of bauxite is 44.6%, the European average content is 53%. Other important composites of bauxite are  $\text{SiO}_2$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{TiO}_2$ .

### 3.2 Aluminium hydroxide

There are various modifications of aluminium hydroxides. The best defined crystalline forms are the three trihydroxides,  $\text{Al}(\text{OH})_3$  gibbsite, bayerite and nordstrandite.

Aluminium hydroxide obtained from the Bayer process is a 99.5% pure white powder. It is either calcinated to aluminium oxide ore sold as wet or dry aluminium hydrate. The specifications of the products of the "Aluminium Oxid Stade GmbH" (AOS) are given in Tab. 3.2.

Tab. 3.1 Product Specification for aluminium hydroxide<sup>4</sup>

| Chemical and physical analysis   |   | Typical Value | Min. Val. | Max. Val. | Quality     |
|----------------------------------|---|---------------|-----------|-----------|-------------|

| Particle size < 45 $\mu\text{m}$ | % | 4             | 1         | 12        | Wet and dry |
| Particle size < 90 $\mu\text{m}$ | % | 45            | 30        | 60        | Wet and dry |

### 3.3 Aluminium Oxide

Hexagonally closest packed aluminium oxide,  $\alpha\text{-Al}_2\text{O}_3$ , is the only stable oxide in the  $\text{Al}_2\text{O}_3\text{-H}_2\text{O}$ -system. The mineral is also called corundum. Corundum is common in igneous and metamorphic rocks. Red and blue varieties of gem quality are called ruby and sapphire, respectively.

The specifications of the  $\text{Al}_2\text{O}_3$  of the "Aluminium Oxid Stade GmbH" (AOS) are given in Tab. 3.2.

### 3.4 Aluminium

Aluminium is a light grey coloured light metal. It has high specific strength, low specific weight, high electrical and thermal conductivity, good ductility or high hardness (depending on alloy) and due to a relatively stable and dense oxide layer on its surface, it exhibits good resistance against corrosion. Some of the most important chemical and physical properties of aluminium are given in Tab. 3.3.

Tab. 3.3 Physical properties of Aluminium

| Property                                             | Value                            | Unit              |
|------------------------------------------------------|----------------------------------|-------------------|
| Atomic number                                        | 13                               | -                 |
| Atomic weight                                        | 27                               | g/mol             |
| Density                                              | 2700                             | kg/m <sup>3</sup> |

| Boiling point                                        | 2467                             | °C                |
| Thermal conductivity (at 20°C)                       | 239                              | W/mK              |
| Modulus of elasticity (99.99% Al)                    | $7.1 \cdot 10^{10}$              | N/m <sup>2</sup>  |
| Tensile strength (99.99% Al, soft / strain-hardened) | $5 \cdot 10^7$ / $13 \cdot 10^7$ | N/m <sup>2</sup>  |
| Tensile strength (Dural)                             | $40 \cdot 10^7$                  | N/m <sup>2</sup>  |
| Specific electrical resistance                       | $2.82 \cdot 10^{-8}$             | Ω m               |

Most technically used aluminium is alloyed. Important alloy elements for aluminium are silicon (Si), zinc (Zn), copper (Cu) and magnesium (Mg). Basically, two types of aluminium alloys are commonly distinguished: wrought alloys and casting alloys. As a rule of thumb, casting alloys tend to have higher contents of non-aluminium metals, especially of iron, silicon and/or zinc, whereas wrought alloys tend to have higher magnesium or sometimes manganese contents.

## 4 Use / Application of Material

### 4.1 Bauxite, aluminium hydroxide and aluminium oxide

About 75% of the bauxite and 90% of the aluminium hydroxide and aluminium oxide is used for aluminium production. Other uses are listed in Tab. 4.1.

Tab. 4.1 Uses of aluminium precursors other than aluminium production

| bauxite          | aluminium hydroxide                             | aluminium oxide                                     |
|------------------|-------------------------------------------------|-----------------------------------------------------|
| Fireproof bricks | Filler for paints                               | Pigment in paints                                   |
| Abrasives        | Filler for paper                                | Filler                                              |
| Catalysts        | Filler for plastics (fire retardant)            | Ceramics                                            |
| Adsorbents       | Raw material for aluminium compounds            | Cosmetics and pharmaceuticals (e.g. sun protection) |
|                  | Cosmetics and pharmaceuticals (e.g. toothpaste) |                                                     |

### 4.2 Aluminium

In 1995, 20.4 Million t of primary aluminium has been used world wide (Mori & Adelhardt (1998)). The amount has increased steadily in the last decades. The biggest consumer of aluminium is the transport industry. Also important are the building and packaging sectors. (See Fig. 4.1 and Fig. 4.2)

Fig. 4.1 Markets for aluminium products in Europe (Estimation EAA)<sup>6</sup>

Secondary aluminium is mainly used in cast alloys because they are less sensitive to high content of silicon and other metals in the scrap and thus can be produced more economically from scrap.

Fig. 4.2 Market for recycled aluminium in Europe in 2000 (estimation EAA)<sup>6</sup>

## 5 System Characterisation

### 5.1 Bauxite mining

This part is mainly based on Mori & Adelhardt (1998).

#### 5.1.1 Production process and infrastructure

More than 95% of the bauxite today is gained from open mines. The thickness of the recoverable ore deposit usually is between 3.5 and 7 meters. The cap of the deposit, which in average is less than one meter thick, is removed as overburden and deposited nearby to be used for the recultivation when the mine has been depleted. The ore is won in stripes using hydraulic excavators and / or belt loaders. Drilling and blasting is only needed in some mines with exceptionally hard bauxite. The bauxite is transported to the mobile grinder and possibly to a dryer from where it is shipped to the aluminium oxide extraction plant.

According to the International Aluminium Institute, about 80% of the bauxite mines are recultivated after their depletion and 97% of the plants have plans for rehabilitating the area currently mined.

#### 5.1.2 Emissions

The only relevant direct emissions from bauxite mining are the dust emissions to air.

#### 5.1.3 Waste

There is no relevant waste produced in the mining process. The overburden is used in recultivation of the mine and not treated as waste although due to finer fractions and possibly increased weathering higher amounts of components of the backfilled material might get into the ground water compared to the situation before the mining activity.

#### 5.1.4 Bauxite mining in ecoinvent

The background information to the processes are given in Tab. 5.1, flows and their sources are shown in:

- |                               |          |
|-------------------------------|----------|
| - bauxite, at mine            | Fig. 5.1 |
| - mine, bauxite               | Fig. 5.2 |
| - recultivation, bauxite mine | Fig. 5.3 |

For a lack of information on this topic, the land use, the size and type of buildings and the weight of the stationary machines used are estimated. The estimation is based on information on other mines (gypsum, limestone).

#### Data quality

Data for bauxite at mine are of good overall quality. The infrastructure is roughly estimated but compared to the actual mining activities the influence is negligible. The values for the mining processes stem from a recent and comprehensive source (Mori & Adelhardt (1998)).

Tab. 5.1 Meta information for the bauxite mining processes

| Name                                  | bauxite, at mine                                                                                                                                                                                                  | mine, bauxite                                                                                                                                                                                                          | recultivation, bauxite mine                                                                                                  |

## 5.2 Aluminium hydroxide and aluminium oxide production

This part is mainly based on information from Aluminium Oxid Stade GmbH<sup>8</sup> and Queensland Alumina Limited<sup>9</sup> and on (Mori & Adelhardt (1998)) and (Hudson et al. (1997)).

### 5.2.1 Production process and infrastructure

#### Overview

98% of the world wide production of aluminium hydroxide and aluminium oxide is based on the Bayer-Process. Austrian Karl-Josef-Bayer received patents in 1887 and 1892 for his process to extract aluminium hydroxide from bauxite using caustic soda.

The aluminium components of bauxite are dissolved by addition of caustic soda. By means of sedimentation and filtration the residue of the digestion is separated. Out of the clear sodium aluminate solution the aluminium hydroxide is precipitated by addition of seeding crystals. After filtration, the aluminium hydroxide is calcined to aluminium oxide at approx. 1000° C. The calcination in the circulating fluidised bed calciner is to remove the water of crystallisation from the hydroxide.

The operation of the process is outlined in Fig. 5.4.

The infrastructure is estimated based on an average sized aluminium oxide refinery (the Aluminium Oxid Stade GmbH (AOS)) in Germany. The plant is spread over an area of 55 hectares. The production was started up at the end of 1973. The nominal production capacity is on a current level of approx. 800'000 metric tons of alumina per year. Fig. 5.5 gives an overview of the refinery.

#### Delivery of raw materials

Most of the refineries are located close to a bauxite mine and / or they have their own port. AOS has a port with outside and inside berth with a usable length of the pier of about 200 m. The unloading is performed by grab with an unloading rate of approx. 600 t/h. The bauxite is transported to the bauxite storage area or the storage building in an enclosed conveyor system.

#### Bauxite storage

AOS open storage capacity is more than 1 mil metric tons. Additionally there is a storage building with approx. 100'000 t capacity.

#### Grinding

The bauxite is ground to a size of maximum 20 mm under addition of recycled digestion liquor (caustic soda solution). Lime can be introduced for phosphate control and mud conditioning. After grinding, the bauxite-liquor mixture (slurry) is pumped into storage tanks.

#### Desilication

The silica component of the bauxite is chemically attacked by caustic soda, causing alumina and soda losses by combining to form solid desilication products. To desilicate the slurry prior to digestion, it is heated and held at atmospheric pressure in pre-treatment tanks, reducing the build-up of scale in tanks and pipes. Most desilication products pass out with the mud waste as sodium aluminium silicate compounds.

---

<sup>8</sup> <http://www.aos-stade.de>, accessed 16.12.2002

<sup>9</sup> <http://www.qal.com.au>, accessed 16.12.02

The bauxite slurry is pumped through the approximately 4'000 m long heat exchanger system of four

Thus about 97% of the aluminium components are extracted from the bauxite. After digestion about 30% of the bauxite mass remains in suspension as thin red mud slurry of silicates, and oxides of iron and titanium. The mud-laden liquor leaving the digestion vessel is flash-cooled to atmospheric boiling point by flowing through a series of flash vessels which operate at successively lower pressures. The energy released by flash evaporation is utilised to pre-heat the bauxite slurry. The condensate generated, which comprises approximately 75 % of the total condensate generated in the plant, is used for washing processes.

### **Dilution**

The bauxite slurry, concentrated by the evaporation of water during digestion, is diluted with wash water from subsequent operations. At AOS 2 dilution tanks with each 1'000 m<sup>3</sup> and a height of 15 m are used. Measured addition of digestion liquor adjusts the desired molar ratio to reduce recovery losses.

### **Red Mud Separation**

The coarse fraction of the undissolved bauxite components (sand) is separated by a hydroseparator and a rake classifier. Next, the slurry flows to the settlers where the remaining undissolved components of the bauxite (bauxite residue (BR) or red mud) are separated by sedimentation. Flocculants might be added to the settler feed stream to improve the rate of mud settling and achieve good clarity in the overflow liquor. The underflow of the settlers is pumped to the first of two washers for pre-washing of the BR. The filtrate is pumped to the washers in a countercurrent stream for dilution. Slaked lime is added to the dilute caustic liquor in the washing process to remove carbonate (Na<sub>2</sub>CO<sub>3</sub>) which forms by reaction with compounds in bauxite and also from the atmosphere and which reduces the effectiveness of liquor to dissolve alumina. Lime regenerates caustic soda, allowing the insoluble calcium carbonate to be removed with the waste mud.

The settled residue from the second washer is pumped to BR filtration, separated by vacuum drum filters and washed with condensate. The filtrate is used in the washer while the filter cake is pumped to the BR disposal area.

### **Liquor Cleaning**

The rest of the undissolved contaminants, such as iron oxide, are substantially filtered out by Kelly filters (pressure filter) using polypropylene filter cloth with aluminium hydroxide as a filter aid. As the contaminants are removed, the aluminium hydroxide is recovered as the filter cake.

### **Liquor Cooling**

The clear supersaturated alumina solution from the top stream of the settlers is cooled down to the temperature required by the precipitation process through multi-stage flash evaporation. Waste heat is used to pre-heat the spent liquor from precipitation.

### **Precipitation**

The cleaned aluminate liquor flows to the agitated precipitation tanks. In these, the super saturated liquor of aluminium hydroxide is seeded (aluminium hydroxide) in two steps and aluminium hydroxide is crystallised over 40-50 hours.

### **Hydroxide Filtration**

The fine fraction of the hydroxide is filtered on disc filters and is returned as seed to the precipitation process. The filtrate, after measured addition of caustic soda, flows back as digestion liquor primarily to the tube digester and grinding facilities. After double filtration and washing, the coarse fraction of the hydrate is calcined, dried, or transported to the hydroxide storage facility.

## **Calcination**

The feed material is calcined to remove both free moisture and chemically-combined water. By calcination, aluminium hydroxide is transformed into aluminium oxide at temperatures around 1'000° C. Calciners can use rotary kilns or the fluid bed process. Fluid bed facilities have proven themselves very reliable, are more energy efficient and don't contaminate the product like the rotary kilns.

Rotary or satellite coolers are used to cool the calcined alumina from the rotary kilns, and to pre-heat secondary combustion air for the kilns. Fluidised-bed coolers further reduce alumina temperature to less than 90°C before it is discharged on to conveyor belts which carry it to storage buildings or silos where it is stockpiled for shipment.

### **5.2.2 Emissions**

#### **Air**

There are no relevant direct air emissions from these processes beside dust from bauxite handling and water from the calcination.

At some sites the area of bauxite unloading and the conveyor belt system for transportation of input materials and products, are enclosed and feature efficient dust removing facilities.

#### **Water**

Process water is recycled. Waste water is created only by the operation of the bauxite residue disposal. Rain water has to be drained from the disposal site. This water is treated before being emitted to nature. After the treatment some NaOH, suspended particles and oxidisable compounds remain in the water.

### **5.2.3 Waste**

Different waste fractions are resulting from the production of alumina. The main part is the red mud or bauxite residue, consisting to about 40 % of water and the other part of mineral matters, being undissolved in the caustic soda - this is principally inert iron and titanium oxides and silica compounds - deriving from the bauxite input. This waste is disposed in special landfills (ponds). Red mud ponds are controlled landfills with base lining and leachate collection. The red mud disposal is therefore inventoried with the model for the residual landfill (Doka (2003), Part III). The red mud is not solidified with cement (like e.g. landfilled incineration residues are). Still the calcium content of red mud is high enough (2.2%) to estimate a carbonate phase of longer than 60'000 years (as in the residual landfill model). No adaptation of transfer coefficients in the model is necessary.

A smaller part is sand waste. For this waste the same composition as for the red mud is assumed.

A generic red mud composition is derived from literature data for red mud from Australia, Jamaica, India, Hungary, Yugoslavia, Turkey, and Suriname (Altundogan et al. (2002), Anonymous (2001), McLaughlin et al. (1998), NPI (1999)). It is given in Tab. 5.2.

Tab. 5.2 Composition of red mud in this project

### 5.2.4 Aluminium hydroxide and aluminium oxide production in ecoinvent

The available information about the infrastructure needed for aluminium oxide production is non-quantitative. Tab. 5.3 and Tab. 5.4 show the details of the assumptions made to estimate the infrastructure expenditures.

Tab. 5.3 Estimated infrastructure for aluminium hydroxide plant

| aluminium hydroxide plant                                                       | Demand        | Unit | Life time | Life time demand |
|---------------------------------------------------------------------------------|---------------|------|-----------|------------------|
| Yearly production capacity                                                      | 1'220'000'000 | kg   | 50        | 1'220'000'000    |
| Area needed without calcination and aluminium oxide storage (95% of total) [m2] | 522'500       | m2   | 50        | 522'500          |
| Administration building (50x50x10 m3)                                           | 25'000        | m3   | 50        | 25'000           |
| Concrete for piers [m3]                                                         | 1'200         | m3   | 50        | 1'200            |
| Grab for unloading [kg]                                                         | 100'000       | kg   | 25        | 200'000          |
| conveyor to bauxite storage [m]                                                 | 300           | m    | 25        | 600              |

| Hydroxide silo (500 t = 500 m3; height 10m radius 4m)                           | 12'315        | kg   | 25        | 24'630           |
| Hydroxide storage hall (6000 t = 6000 m3, average height 10 m)                  | 600           | m2   | 50        | 600              |

Tab. 5.4 Estimated infrastructure for aluminium oxide plant

| aluminium oxide plant                                                      | Demand      | Unit | Life time | Life time demand |
|----------------------------------------------------------------------------|-------------|------|-----------|------------------|
| Yearly production capacity                                                 | 800'000'000 | kg   | 50        | 800'000'000      |
| Area needed for calcination and aluminium oxide storage (5% of total) [m2] | 27'500      | m2   | 50        | 27'500           |
| 3 fluid bed calciners                                                      | 20'000      | kg   | 25        | 40'000           |
| Concrete silo (65000 m3; height 25 m, radius 30m)                          | 1'555       | m3   | 50        | 1'555            |
| Steel silo (2000 m3, height 15 m, radius 6.5m)                             | 30'733      | kg   | 25        | 61'465           |
| conveyor belt                                                              | 100         | m    | 25        | 200              |

The other background information to the processes is given in Tab. 5.5, flows and their representation in the database is shown in:

- aluminium hydroxide, at plant Fig. 5.6
- aluminium hydroxide, plant Fig. 5.7
- aluminium oxide, at plant Fig. 5.8
- aluminium oxide, plant Fig. 5.9

### Data quality

Data for the steps in the aluminium oxide production are of good overall quality. The infrastructure is roughly estimated but compared to the other activities the influence is negligible. The values for the processes stem from a recent and comprehensive source (EAA (2000)).

Tab. 5.5 Meta information for the aluminium hydroxide and aluminium oxide processes

| Name                                  | aluminium hydroxide, at plant                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     | aluminium hydroxide, plant                                                                                                                                                                                  |

| General Comment to reference function | $\text{Al}(\text{OH})_3$ extraction and calcination to $\text{Al}_2\text{O}_3$ is done in the same plant in line. Only cumulated data for the whole process are available. In- and outputs of $\text{Al}(\text{OH})_3$ are calculated according to the stoichiometry ( $1.530 \text{ kg } \text{Al}(\text{OH})_3 \rightarrow 1.000 \text{ kg } \text{Al}_2\text{O}_3 + 0.530 \text{ kg } \text{H}_2\text{O}$ ). Weak data for the energy consumption fractions of the two process parts were available. It is however not known if they relate to wet or dry aluminium hydroxide. | Medium sized plant. Output: 1'220'000 t/a, life time: 50 years                                                                                                                                              |

| General Comment to reference function | $\text{Al}(\text{OH})_3$ extraction and calcination to $\text{Al}_2\text{O}_3$ is done in the same plant in line. Only cumulated data for the whole process are available. In- and outputs of $\text{Al}(\text{OH})_3$ are calculated according to the stoichiometry ( $1.530 \text{ kg } \text{Al}(\text{OH})_3 \rightarrow 1.000 \text{ kg } \text{Al}_2\text{O}_3 + 0.530 \text{ kg } \text{H}_2\text{O}$ ). Weak data for the energy consumption fractions of the two process parts were available. It is however not known if they relate to wet or dry aluminium hydroxide. | Medium sized plant. Output: 800'000 t/a, life time: 50 years                                                                                                         |

## 5.3 Primary aluminium

This part is mainly based on (Hudson et al. (1997)) and (Mori & Adelhardt (1998)).

### 5.3.1 Production process and infrastructure

All commercial production of aluminium today is done in Hall-Héroult cells. Two major types of cells are currently in use: those employing prebaked carbon anodes and those employing self-baking Söderberg anodes. The Hall-Héroult cell with prebaked anodes is shown in Fig. 5.10. Essentially pure alumina is fed into the cryolite base electrolyte. Electric current deposits aluminium into a pool of molten aluminium held under the electrolyte in the carbon lined cavity of the cell. Oxygen from the alumina deposits electrolytically onto the carbon anode dipping into the electrolyte and reacts with (burns) the anode. Cells typically range from 9 to 12 m long, 3 to 4 m wide, and 1 to 1.2 m high. Thermal insulation surrounds the carbon lining of the cell to control heat losses. Although carbon is the material known to withstand best the combined corrosive action of molten fluorides and molten aluminium, even carbon would have a very limited life in contact with the electrolyte at the sides of the cell were it is not protected by a layer of frozen electrolyte. The thermal insulation is adjusted carefully to maintain a protective coating on the walls but not on the bottom, which must remain substantially bare for electrical contact. Steel collector bars in the carbon cathode conduct electric current from the cell. These bars are inserted into holes that have been sized carefully so that thermal expansion forms a tight electrical contact, or cemented in place with carbonaceous cement containing metal particles, or bonded in place with cast iron.

The electrical resistivity of prebaked anodes ranges from 0.005 to 0.006  $\Omega \cdot \text{cm}$ . Current density at the anode face is 0.6 – 1.3  $\text{A}/\text{cm}^2$ .

The Söderberg anode uses a premixed "paste" of petroleum coke and coal-tar pitch. This mixture is added at the top of a rectangular steel casing that is typically 6 – 8 m long, 2 m wide, and 1 m high. Heat from the electrolyte and heat from the electric current passing through the anode bakes the carbonaceous mix as it progresses through the casing.

The baked portion extends past the casing and into the molten electrolyte. Baked mix replaces anode being consumed at the bottom surface. Electric current enters the anode through either vertical or sloping steel spikes. These spikes are pulled and reset to a higher level as they approach the lower surface. Söderberg anodes have an electrical resistivity about 30 % higher than that of prebaked anodes. Because of the resulting lower power efficiency and the greater difficulty in collecting and disposing of baking fumes, Söderberg anodes are being replaced by prebaked anodes, even though the former save the capital, labour, and energy required to manufacture the latter.

**Fig. 5.10 Hall-Héroult cell with prebaked anode:** a) carbon anode b) electrolyte, c) insulation, d) carbon lining, e) current collector bar, f) thermal insulation, g) steel shell, h) carbon block, i) ledge, j) crust, k) aluminium oxide cover, l) removable covers, m) anode rods, n) fume collection, o) air cylinder, p) feeder, q) current supply, r) crust breaker

Metal tapped from the Hall-Héroult cell may be treated in one of several ways. First, it may be transported in the molten state to a holding furnace, where, along with solid scrap, it is alloyed, fluxed, filtered, and cast into a form suitable for fabrication by rolling, forging, etc., or for remelting by a foundry. It may be transported further (over distances up to 200 km) on trucks, equipped with well-insulated containers to prevent freezing, to a foundry where it is alloyed and used to make shaped castings. Both these methods of utilizing the molten metal are favoured because energy required for remelting is conserved.

Alternatively, where ingot casting facilities or foundries are not nearby, metal is cast using cast iron moulds into "primary" ingots for remelting. Generally, these unalloyed remelt ingots come as stackable 22-, 340-, or 680-kg ingots. Casting machines are often fully automated, with production rates of up to 20000 kg/h.

Infrastructure is estimated based on information of an average sized electrolysis plant with cast house in Norway. Production capacity is about 130'000 t/year. About 3'000 tons is secondary material (for alloying) that can be neglected for our purpose. The aluminium is cast in 7 meter long billets with a diameter that varies between 178 and 314 mm. Later the billets are sawed, packed and driven to the quay for shipment. The most important data about the plant are given in Tab. 5.6.

**Tab. 5.6 Infrastructure data for a medium sized electrolysis plant with cast house (Soral)<sup>10</sup>**

|                      |                             |
|----------------------|-----------------------------|
| Production Capacity  | 130.000 tons                |
| Area:                | 976,000 m <sup>2</sup>      |
| Length -Pot-rooms    | 857 m                       |
| Breadth- Pot-rooms   | 23 m                        |
| Electrolysis pots    | 320                         |
| Cast -house          | 12.200 m <sup>2</sup>       |
| Height- Silos        | 55 m and 62 m               |
| Capacity-Silos       | 30.000 tons and 40.000 tons |
| Length-Conveyor Belt | 900 m                       |
| Length-Quay          | 240 m                       |
| Capacity-Quay        | 70.000 tdw                  |
| Storage house        | 9500 m <sup>2</sup>         |

### 5.3.2 Emissions

#### Air

Relevant direct air emissions from the anode production (baking) and from the electrolysis itself are CO, CO<sub>2</sub>, fluorides, dust, polycyclic aromatic hydrocarbons, Nitrogen oxides and sulphur oxides. The casting is responsible for some direct fluoride emissions. The other processes don't emit to air directly.

#### Water

There are no relevant direct water emissions from these processes

### 5.3.3 Waste

Several different waste streams are generated. Some of them are recycled or reused and thus not inventoried. The others are deposited in landfills. (See Fig. 5.11, Fig. 5.12, Fig. 5.13 and Fig. 5.14)

#### Anode production waste

In the anode production carbon and tar wastes are produced. The compositions are unknown. 100% carbon is assumed for tar. A certain amount of waste might be recycled. However, since no data on the share to recycling is available, disposal in a residual material landfill is assumed.

The "carbon waste" refers to the waste of the anode butt recycling. Thus it is inventoried the same way as the carbon fraction of spent pot lining.

#### Cathode production waste

Because the cathode production includes the disposal of the old cathode, the waste of this process is basically the spent pot lining. It is separated into a carbon fraction (1<sup>st</sup> cut) and refractory (brick) fraction (2<sup>nd</sup> cut). A certain amount of these wastes might be recycled. However, since no data on the share to recycling is available, both wastes are assumed to be landfilled in a residual material landfill. The ranges for their chemical composition that were presented by R. P. Pawlek at the 10<sup>th</sup> international Al symposium in 1999<sup>11</sup> and the values used in this project are given in Tab. 5.7.

#### Electrolysis waste

The carbon waste of the electrolysis is basically the waste fraction from used anodes that can't be recycled. It is inventoried as the carbon fraction of SPL.

<sup>11</sup> <http://www.aluminium.sk/prednasky/32.htm>, accessed 19.12.2002

### Aluminium casting waste

The fibre and refractory wastes of the casting process are inventoried as inert material to landfill. The dross composition given in

Tab. 5.8 stems from the environment agency of the UK<sup>12</sup>. Disposal in a residual material landfill is assumed.

Data for the filter dust composition are given in Tab. 5.9. Disposal in a residual material landfill is assumed.

**Tab. 5.7 Composition of spent pot liner**

### 5.3.4 Primary aluminium in ecoinvent

The available information about the infrastructure needed for aluminium production is non-quantitative. Tab. 5.11 and Tab. 5.12 show the details of the assumptions made to estimate the infrastructure expenditures.

Tab. 5.10 Estimated infrastructure for anode plant

| anode, plant                                       | Demand     | Unit           | Life time | Life time demand |
|----------------------------------------------------|------------|----------------|-----------|------------------|
| Yearly production capacity                         | 80'000'000 | kg             | 50        | 80'000'000       |
| Area of plant (assumption based on casting plant)  | 300'308    | m <sup>2</sup> | 50        | 300'308          |

The other background information to the processes is given in Tab. 5.13, flows and their representation in the database is shown in:

- anode, aluminium electrolysis Fig. 5.11
- anode, plant Fig. 5.12
- cathode, aluminium electrolysis Fig. 5.13
- aluminium, primary, liquid, at plant Fig. 5.14
- aluminium electrolysis, plant Fig. 5.15
- aluminium, primary, at plant Fig. 5.16
- aluminium casting, plant Fig. 5.17

### Data quality

Data for the steps in the primary aluminium production are of good overall quality. The infrastructure is roughly estimated but compared to the other activities the influence is negligible. The values for the processes stem from a recent and comprehensive source (EAA (2000)).

Tab. 5.13 Meta information for the aluminium electrolysis and casting processes

| Name                                  | anode, aluminium electrolysis                                                                                    | anode, plant                                                                                                | cathode, aluminium electrolysis                                                                                                                                                                                                                                                                                                              |

| Included Processes                    | Includes anode production (with its plant), transports of materials to the plant and the disposal of the wastes. | Production hall, machinery and administrative buildings (including disposal)                                | Includes cathode production and removal, transports of materials to the plant and the disposal of the wastes. Because the cathode is produced in the electrolysis plant, no cathode production plant is balanced. No data have been found on air emissions from baking. It is assumed that these emissions are included in the electrolysis. |

## 5.4 Secondary aluminium

This part is mainly based on EAA (2000).

### 5.4.1 Production process and infrastructure

A wide variety of aluminium scrap is processed in the secondary aluminium industry. A basic differentiation is made between "new" and "old" scrap.

New scrap is surplus material that arises during production and fabrication of aluminium products up to the point where they are sold to the final consumer. It is usually of known quality and alloy and often uncoated. It can then be remelted with little preparation. Some new scrap is coated with paints or plastics. This scrap has to be de-coated in an oven or a mesh conveyer where the coatings are volatilised or burned.

Old scrap or post-consumer scrap is the aluminium recovered after the product has been used by the final consumer. It comes into the secondary aluminium industry via metal merchants and waste management companies which recover aluminium from e.g. vehicles, household goods etc. This is usually done by shredding, magnetic separation and sink-and -float installations or eddy current installations successively. Old scrap is usually recycled together with two-thirds of new scrap from aluminium processing.

Different melting processes are used depending on composition of the scrap, process availability and economics amongst other variables. Molten metal fluxing and filtration technologies are used for quality control of the resulting alloys.

### 5.4.2 Emissions

#### Air

If new scrap is clean and uncoated no emissions arise from cleaning or de-coating. Melting and alloying of new scrap emits HCl and chlorides. Old scrap preparation leads to dust and also HCl and chloride emission. Melting and alloying of old scrap leads to dust and different inorganic emissions.

The size fractions of the dust emissions are derived by the medium level emissions in cepmeip emission factor database<sup>14</sup>.

#### Water

There are no reports of direct water emissions from these processes. The preparation of old scrap however is expected to emit certain substances to water.

### 5.4.3 Waste

#### New scrap production waste

In the preparation of uncoated new scrap no waste is generated.

#### Aluminium from new scrap production waste

The secondary aluminium production from new scrap generates only some refractory material waste which is inert and deposited in landfills.

#### Old scrap production waste

The preparation of old scrap generates different waste fractions:

---

<sup>14</sup> [http://www.air.sk/tno/cepmeip/em\\_factors\\_results.php?](http://www.air.sk/tno/cepmeip/em_factors_results.php?), accessed 08.01.03

- Waste oil is assumed to be deposited as hazardous waste in an underground deposit.
- No composition data could be found for ball mill dust, waste filter materials and waste sediments. All the fractions are assumed to consist mainly of organic coatings of the scrap and to a lower extent of aluminium oxide. Deposition as hazardous waste in an underground deposit is assumed.
- Dirt is assumed to be an inert waste deposited in inert material landfills.
- Filter dust composition is assumed to be the same as in the electrolysis process (see Tab. 5.9). Disposal in a residual material landfill is assumed.

#### Aluminium from old scrap processing waste

The secondary aluminium production from old scrap also generates "ball mill dust" and "filter dust". These wastes are treated as the respective wastes from the old scrap production.

#### 5.4.4 Secondary Aluminium in ecoinvent

The available information about the infrastructure needed for aluminium production is non-quantitative. Tab. 5.14 and Tab. 5.15 show the details of the assumptions made to estimate the infrastructure expenditures.

Tab. 5.14 Estimated infrastructure for aluminium melting furnace

| aluminium melting furnace                         |            | Unit | Life time [a] | Life time demand |
|---------------------------------------------------|------------|------|---------------|------------------|

### Data quality

Data for the steps in the secondary aluminium production are of satisfactory overall quality. The values for the smelting processes stem from a recent and comprehensive source. The proxies chosen to represent the alloying elements in ecoinvent however are decreasing the overall quality. The collection of the scrap and the infrastructure are roughly estimated. The infrastructure is of minor importance compared to the other activities but the transports (scrap collection) could have a noticeable impact.

## 5.5 Aluminium production mix

The share of primary and secondary metal on the world wide production of different aluminium alloys is given in Tab. 5.17. These mixes are proposed to be used in attributional LCA, if the scope of the study does not imply a special share of secondary material for a certain product. They are used as default within the ecoinvent database. In consequential LCA the value corrected substitution as proposed in Werner (2003); Werner & Richter (2000) might be better suited for modelling the life cycles of aluminium products.

Tab. 5.17 Production mix of "average" aluminium alloys<sup>15</sup>

| Alloy         | primary aluminium | secondary aluminium<br>from new scrap | secondary aluminium<br>from old scrap | Share on production |
|---------------|-------------------|---------------------------------------|---------------------------------------|---------------------|
| Cast alloy    | 20 %              | 47 %                                  | 33 %                                  | 31 %                |
| Wrought alloy | 90 %              | 10 %                                  | 0 %                                   | 69 %                |
| Unspecific    | 68 %              | 22 %                                  | 10 %                                  | 100 %               |

### 5.5.1 Aluminium production mixes in ecoinvent

The background information to the processes are given in, flows are shown in Tab. 5.18:

- aluminium, production mix, cast alloy, at plant Fig. 5.24
- aluminium, production mix, wrought alloy, at plant Fig. 5.25
- aluminium, production mix, at plant Fig. 5.26

#### Data quality

The shares are estimates. Nevertheless they are believed to give a good representation of the overall situation.

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1

## Comments on version 2.1

This part corresponds to the original report in Althaus et al. (2004) that has been updated with the changes reported in Frischknecht et al. (2006). The changes concerned emission factors for dioxine (factor 1000 reduced in sinter, pellet and pig iron), PAH (factor 1000 lower in pellet) and CO<sub>2</sub> (factor 1000 in pig iron), as electricity demand (factor 3.6 lower in cast iron, electric steel, both chromium and un- / low alloyed) and coke consumption for pig iron (factor 28.6 higher).

In version 2.0, changes have been made to the following datasets:

- iron ore, 65% Fe, at beneficiation / GLO [kg]:  
all water emissions decreased approx. a factor of 100
- sinter, iron, at plant / GLO [kg]:  
PAH and PCB emissions decreased by a factor of 1000. VOC emissions increased slightly due to decreased PAH and PCB.
- pig iron, at plant / GLO [kg]:  
additional demand of 0.12 MJ natural gas,  
higher waste heat generation (accordingly),  
slightly higher transports due to increased coke consumption,  
higher amount of waste water to treatment (factor 1000)  
and higher CO<sub>2</sub> emission (approx. factor 2; newly calculated from C-balance)
- steel, electric, un- and low-alloyed, at plant / RER [kg]  
transports decreased by a factor of approx. 8
- steel, electric, chromium steel 18/8, at plant/ RER [kg]  
transports decreased by a factor of approx. 8
- cast iron, at plant/ RER [kg]  
transports decreased by a factor of approx. 8

Chapter “6 Cumulative Results and Interpretation” of the original report has not been adapted and was deleted for this report. The flow names in the tables displaying unit process data have been updated with the actual names of version 2.0. This affects the designation of namely the transportation service flows that have been changed respective to the preceding version.

## Comments on this version 2.1

This version corresponds to the version 2.0 with a changed composition of low alloyed steel.

## Summary

The steel production is modelled for the European situation, primarily based on data from the description of the current situation in the “Best Available Techniques Reference Document on the Production of Iron and Steel” IPPC (2000) and on process descriptions.

The mining, beneficiation and partly the sinter and pellet production represent a world-wide situation primarily based on Roth et al. (1999).

Some of the datasets described in this report make only sense in the context of the steel production and are therefore not intended for other uses.

The datasets to be chosen to represent iron or steel in a LCA study are either one of the primary (converter) steel datasets (chapter 5.6), one of the secondary (electric) steel datasets (chapter 5.7), the cast iron (chapter 5.8) or one of the production mixes (chapter 5.9). The decision whether to use primary, secondary or a mix of the two depends on the goal and scope of the LCA to be conducted.

# 1 Introduction

This part deals with primary and secondary iron and steel production. A rough overview of the cradle to gate processes of the cast iron and steel production are given in Fig. 1.1.

**Fig. 1.1** Overview of cast iron and steel production (The grey materials and processes are of minor relevance and not considered in the ecoinvent data)

## 2 Reserves and Resources of Materials

Iron is the 4<sup>th</sup> most common element in the outer earth crust. It occurs in nature in compounds with other elements. The economically most important iron minerals are hematite and magnetite.

Iron ore is mined mainly in China, Brazil and in Australia. (Tab. 2.1). The yearly iron ore production was about  $1 \cdot 10^9$  t/a in 1996 and the estimated reserves are about  $150 \cdot 10^9$  t. (Roth et al. (1999))

**Tab. 2.1 World wide iron ore production in 1996 (Roth et al. (1999), appendix 2 & 4)**

|                                     | <b>Western Europe</b> | <b>Eastern Europe</b> | <b>Asia</b> | <b>Africa</b> | <b>Northern America</b> | <b>South America</b> | <b>Australia</b> | <b>World</b> |
|-------------------------------------|-----------------------|-----------------------|-------------|---------------|-------------------------|----------------------|------------------|--------------|
| Iron ore [% of world production]    | 3%                    | 12%                   | 34%         | 5%            | 9%                      | 22%                  | 15%              | 100%         |
| Iron in ore [% of world production] | 4%                    | 12%                   | 25%         | 5%            | 11%                     | 26%                  | 17%              | 100%         |
| Iron concentration in ore [%]       | 57%                   | 54%                   | 39%         | 61%           | 64%                     | 65%                  | 63%              | 54%          |

Most of the iron ore is reduced to iron in blast furnaces. About 0.5 kg of coke and smaller amounts of other fossil energy carriers and electricity are needed for the reduction.

Iron and steel scrap are also important resources because of the lower primary energy consumption and lower CO<sub>2</sub> emissions, compared to the blast furnace – converter production route. The share of secondary iron on the European market is 34% according to Frischknecht et al. (1996) and the world average of steel scrap used in steel production is about 40% Steffen (1997).

## 3 Characterisation of the materials

### 3.1 Iron ore

Iron ores are mixtures of up to 400 different minerals. The most important ones are the iron oxides and sulphides. Economically interesting are those ores with high iron content. Two third of the ore mined today come from banded iron formations (BIF). The average iron content of BIF's is between 15% and 45% but the more interesting ores contain up to 68% iron. Although the world average iron content in the ores mined in the years 1975 to 1996 is 56% (calculated from Roth et al. (1999), appendices 1 - 4), the iron content of raw ores used for the input- output tables in Roth et al. (1999) is only 46%. The authors don't mention this discrepancy. It is likely that different methods of calculation are responsible for it. In the ecoinvent inventories we use an iron content of 46% to be compatible with the flow data given in Roth et al. (1999).

An enrichment of this ore to an iron content of 65% in world average is done at the mine. 13% of the enriched ore are big lumps that can be fed to the blast furnace directly. The rest is more or less fine grade ore that has to be agglomerated to sinter or pellets for use in the blast furnace.

### 3.2 Sinter and Pellets

As a rule, blast-furnace burden contains lump ore, sinter, and pellets. Pellets are made from both concentrate and iron-rich fine ore. If the beneficiation process yields very fine-grained concentrates (e.g., <0.1 mm), these are usually converted to pellets at the mine and transported in this form. Sinter is generally produced at the ironworks. The varying loads imposed on material during transport to the blast furnace mean that pellets must satisfy stringent mechanical strength requirements. Pellets are also nearly always made from one well-defined ore or concentrate, whereas sinter is produced from pre-designed mixtures of ores and additives.

Sinter and pellets differ in the way the particles are bound into the agglomerate:

In pellets, the ore particles are connected chiefly by bridges of ore. The formation of iron oxide bridges is supported by additional slag bridges; it must be remembered that the quantity of slag in many pellet qualities is only 3 – 4 % (w/w) (corresponding to 6 – 7 % (v/v)).

Sinter consists of a calcium ferrite matrix, with siliceous and aluminous constituents dissolved and primary hematite embedded in it. Whereas pellets are thoroughly oxidised (a maximum of 0.5 % (w/w) FeO), sinter contains 4 – 6 % (w/w) FeO, which is linked to silica and aluminium oxide in the matrix. (Meiler (1997))

### 3.3 Hot metal / Pig iron

Pig iron is the iron produced in the blast furnace. It is an alloy of 94% Fe and more than 2% C (world average 4.5%). Liquid pig iron is also referred to as "hot metal".

### 3.4 Sponge iron

Sponge iron is produced by direct reduction of iron ore in the solid state. This process is only possible with special ores with high iron content and low content on acid slag components. About 6% of the total world pig iron and sponge iron production is sponge iron.

### 3.5 Cast iron

The term cast iron is used for unalloyed, low-alloy, and highly alloyed iron – carbon cast material with carbon content ca. 2.8 – 4 %. The carbon is for the most part not chemically bonded to the iron, but is

present in elemental form. The properties of cast iron can be modified within wide limits by adding elements such as nickel, chromium, manganese, copper, and silicon, which change the metallic structure. Corrosion-resistant and high-temperature grades are used, e.g., in the chemical industry, in furnaces, and in the automobile industry. The cryogenics industry uses low-temperature grades that do not become brittle at temperatures far below 0 °C. Other important characteristics include its property of damping vibration, its good resistance to corrosion by weathering, and its good machining properties. (Kucharcik (1997))

## 3.6 Steel

Steels are forgeable iron alloys with a carbon content of less than 2.1% (w/w). More than 90% of the world iron production is used for steel making and more than 3500 different grades of steel are available today<sup>1</sup>.

The following iron-bearing materials are used for crude steel production:

- Iron melt from blast furnaces (hot metal), mainly used for steel production by the basic oxygen furnace (BOF) process.
- Scrap, sponge iron, and solidified blast-furnace iron (pig iron), mainly used for melting steel in electric furnaces.

According to the production process, steels can be classified as converter (BOF) or electric steel.

### 3.6.1 Unalloyed steel

Unalloyed steels or carbon steels are those in which the level of an individual element in no case reaches or exceeds the limiting concentration given in Tab. 3.1 (Kalla & Kalwa (1997)). Typical unalloyed steels are the reinforcement steels used in the building industry.

**Tab. 3.1 Limiting concentration of elements in unalloyed steel according to EN 10 020 Kalla & Kalwa (1997)**

| Element            | Al              | B      | Bi   | Co   | Cr <sup>1</sup> | Cu <sup>1</sup> | La             | Mn                | Mo <sup>1</sup> | Nb <sup>2</sup>     |
|--------------------|-----------------|--------|------|------|-----------------|-----------------|----------------|-------------------|-----------------|---------------------|
| max. concentration | 0.10            | 0.0008 | 0.10 | 0.10 | 0.30            | 0.40            | 0.05           | 1.65 <sup>3</sup> | 0.08            | 0.06                |
| Element            | Ni <sup>1</sup> | Pb     | Se   | Si   | Te              | Ti <sup>2</sup> | V <sup>2</sup> | W                 | Zr <sup>2</sup> | Others <sup>4</sup> |
| max. concentration | 0.30            | 0.40   | 0.10 | 0.50 | 0.10            | 0.05            | 0.10           | 0.10              | 0.05            | 0.05                |

<sup>1</sup> If two, three or four of these elements are present in concentrations less than the maximum permitted, their total concentration must not exceed 70% of the sum of the maximum

<sup>2</sup> The same rule applies to these elements

<sup>3</sup> If the manganese content is quoted as minimum, this value applies

<sup>4</sup> Except C, N, O and S

### 3.6.2 Low-alloyed steel

Low-alloy steel contains more than the minimum given in Tab. 3.1 of at least one of the elements and less than 5% alloying elements in total.

<sup>1</sup> <http://www.worldsteel.org/understanding/18>; accessed 15.01.2003

For this project a composition of the average low-alloyed steel is derived from literature and from the production volumes of the different alloying elements. Tab. 3.2 shows the composition and the sources of the individual numbers.

**Tab. 3.2 Composition of low-alloyed steel**

| Element | concentration | Source                                                                                                                                                                                                                                                                                                                 |

### 3.6.3 Stainless steel

Stainless steel is the generic name for a number of different steels used primarily for their resistance to corrosion. The one key element they all share is a minimum of 10.5% (w/w) of chromium. Although other elements, particularly nickel and molybdenum, are added to improve corrosion resistance, chromium is always the deciding factor. The vast majority of steel produced in the world is carbon and alloy steel, with the more expensive stainless steels representing a small, but valuable niche market<sup>6</sup>. Of all the stainless steels the grade 304 steel (18/8 stainless, 18% chromium 8% nickel) is most commonly used. Typical applications for this grade are cutlery, food and chemical production infrastructure and containers and more and more architectural applications.

In this project we balance only 18/8 stainless steel.

## **4 Use / Application of Material**

### **4.1 Iron ore**

Most of the iron ore is used for iron and steel production.

### **4.2 Pig iron / hot metal**

Most of the pig iron is used for steel production before it is solidified. A smaller part is cast to ingots that are used for cast iron production later.

### **4.3 Cast iron**

About 40 % of cast iron is used in the automobile industry. Other applications include mechanical engineering, the building industry (e.g. radiators, boilers, sanitary ware and pipes), chemical plant, ship-building, and mining. The former demand by steelworks for cast iron ingot moulds has been greatly diminished by the introduction of the continuous casting process. (Kucharcik (1997))

### **4.4 Steel**

Steel is one of the most important materials in the industrialised world. It is widely used in all industries and in many products. The yearly world steel production has risen exponentially between 1940 and 1970 to about 700 million tonnes. Since then it has shown a slight increase to about 850 million tonnes in the year 2000.

#### **4.4.1 Unalloyed and low-alloyed steel**

Unalloyed steel is mainly used as reinforcing steel in the building industry. There are many other applications in industrial machines, vehicles etc. for unalloyed and low-alloyed steel.

#### **4.4.2 Stainless steel**

Stainless steel is often used in the chemical and food industry. Again there are many other applications for stainless steel.

## 5 System Characterisation

### 5.1 General overview

A rough overview of the cradle to gate processes of the cast iron and steel production are given in Fig. 5.1.

Fig. 5.1 Overview of cast iron and steel production (The grey materials and processes are of minor relevance and not considered in the ecoinvent data)

### 5.2 Iron ore mining and beneficiation

This part is mainly based on (Roth et al. (1999)) and (Meiler (1997)).

#### 5.2.1 Production process and infrastructure

Most of the iron ore today is gained from open mines. The thickness of the recoverable ore deposit usually is in the range of 100 meters. The cap of the deposit is removed as overburden and deposited nearby to be used for the recultivation when the mine has been depleted. The ore is won in stripes us-

ing hydraulic excavators and / or belt loaders. Drilling and blasting is needed in some mines with hard ore.

The only processing steps used for ores mined from rich deposits (rich ores) are crushing and screening. Such ores come mainly from the weathering zones of itabirite deposits. At some mines, washing is combined with the screening of fines ( $< 6 - 8$  mm) for sintering; very fine material containing kaolin is thus separated, and the aluminium oxide content is reduced. Low-grade ore is concentrated to lower transport costs and bring about a chemical composition suitable for the subsequent reduction step (lower silica content). The concentration of iron ore is generally based on physical differences between the iron-bearing and gangue minerals (spec. weight, magnetic properties).

Harmful components present in the ore must be removed. Such components include phosphorus, arsenic, chromium, copper, vanadium, alkali, sulphur and titanium; these either make metallurgical processing more difficult or degrade the iron and steel quality. A small quantity of titanium ( $< 0.5$  %) is, however, added to the burden at some ironworks, because it has been found to increase the life of the blast-furnace brickwork.

### **5.2.2 Emissions**

#### **Air**

The only relevant direct emissions to air from iron ore mining and beneficiation are the dust emissions.

#### **Water**

Heavy metal and hydrocarbon emissions to water occur in the beneficiation process. They are estimated according to the maximum values given in Anonymous (1998)

### **5.2.3 Waste**

There is no relevant waste produced in the mining and beneficiation process. The overburden is used in recultivation of the mine and not treated as waste.

### **5.2.4 Iron ore mining and beneficiation in ecoinvent**

The background information to the processes are given in Tab. 5.1, flows are shown in:

- |                                      |          |
|--------------------------------------|----------|
| - iron ore, 46% Fe, at mine          | Fig. 5.2 |
| - mine, iron                         | Fig. 5.3 |
| - recultivation, iron mine           | Fig. 5.4 |
| - iron ore, 65% Fe, at beneficiation | Fig. 5.5 |

For a lack of information on this topic, the land use, the size and type of buildings and the weight of the stationary machines used in the iron mines are estimated. The estimation is based on information on other mines (gypsum, limestone).

**Tab. 5.1 Meta information for the iron ore mining and beneficiation processes**

|                                       |                                                                                         |                                                                                                                                                                                                    |                                                                                                                                                                                                                                                                                                                         |                                                                                                    |

| General Comment to reference function |                                                                                         | It is assumed, that the crude ore residues are used for recultivation. The same amount of energy used in building machines that is used per kg crude ore is used per kg residue for recultivation. | This ore has different grain sizes. It can be lump ore that can be used directly in the blast furnace or it can be ore of smaller grain size that is used for sinter and pellet production. Water emissions are estimated according to the maximal levels for financial support of mining activities by the world bank. | These data are a rough assumption. Yearly output is 40000000000 kg, life Time 30 years             |

### **Data quality**

Data uncertainty is derived using the Pedigree matrix as described in (Frischknecht et al. (2003)) except for the recultivation of the mine and for the mine infrastructure where this method would result in values far too low.

Data for iron ore mining are of good overall quality although the infrastructure is roughly estimated. Water emission data for beneficiation are based on threshold values and thus exhibit a greater uncertainty.

## **5.3 Agglomeration: sinter and pellet production**

This part is mainly based on information from (Meiler (1997)).

### **5.3.1 Production process and infrastructure**

Very fine material is undesirable in the reduction equipment. Modern high-performance blast furnaces require physical and metallurgical preparation of the burden. Agglomeration on one hand is used as a process of size enlargement aimed at improving the permeability of the blast-furnace burden. On the other hand slagging materials are introduced via the agglomerates.

As a rule, blast-furnace burden contains lump ore, sinter, and pellets. Pellets are made from both concentrate and iron-rich fine ore. If the beneficiation process yields very fine-grained concentrates (e.g., <0.1 mm), these are usually converted to pellets at the mine and transported in this form. Sinter is generally produced at the ironworks. The varying loads imposed on material during transport to the blast furnace mean that pellets must satisfy stringent mechanical strength requirements. Pellets are also nearly always made from one well-defined ore or concentrate, whereas sinter is produced from pre-designed mixtures of ores and additives.

Sinter and pellets differ in the way the particles are bound into the agglomerate. Pellets are burned at a temperature below the melting points of the constituents. Their strength gain is adequate only when the reaction temperature is controlled to  $\pm 10$  °C over long time periods. For this reason, hot gas is used to supply heat; it can be generated by the combustion of fuel gas, oil, or even coal. In sintering, on the other hand, the constituents of the mixture are melted. This happens at temperatures so high that the reaction itself goes to completion within minutes, but in a thin layer that continuously advances through the material bed concurrently to the gas.

In pelletising spherical green pellets (green balls) of appropriate size (ca. 9 – 16 mm in diameter) are first formed by a pelletising disk or drum. Then the pellets are thermally hardened of at 1200 – 1320 °C.

Iron-ore sinters are virtually all produced in travelling-grate installations. Along with ore and concentrate, the mixture for sintering also contains recycle material from the ironworks, provided no build-up of undesirable or detrimental substances results.

Coke is the dominant sinter plant energy input (about 85%), with electricity and gas (COG and/or BF gas and/or natural gas) supplying the remainder in equal shares (IPPC (2000)).

### **5.3.2 Emissions**

#### **Air**

Sintering and pelletising leads to the emission of dust, various heavy metals and hydrocarbons, hydrogen halogenides, NO<sub>x</sub>, SO<sub>x</sub> and CO<sub>2</sub> from the burning of the fuel gas and some of the coke. These pro-

cesses are also a major source of dioxide emissions. The dioxin emission value for the sinter production stems from (Anonymous (2002)).

Dust grain size analysis before treatment shows two distinctive peaks. The first and higher peak is at about 1  $\mu\text{m}$  while the second one is at 100  $\mu\text{m}$  (IPPC (2000)). The abatement used in sinter plants has a high efficiency in removing the larger particles while the smaller alkali and lead chlorides are hard to remove in the electrostatic precipitators due to their high resistivity. Thus a particle size of < 2.5  $\mu\text{m}$  is assumed for the dust emission after abatement.

## **Water**

The water used in the agglomeration processes evaporates. Thus no relevant water emissions occur.

### **5.3.3 Waste**

Normally all solid wastes originating from the agglomeration plant (dusts from de-dusting devices and sieving fractions) are recycled to the strand. However, in sinter plants there can be two exceptions: The first concerns sludge from wet waste gas treatment systems, which is put to landfill. At present, there are only two plants in Europe operating such a system. The second exception is filter dust from the last field of electrostatic precipitators (ESP). Most European sinter plants are operated with fully closed dust cycles. However, some plants exclude fine dust from the last field of the ESP. This dust mainly consists of alkali and metal chlorides. This so-called partly open filter dust cycle is carried out in order to improve the operation of ESP or (in one case) of the bag filter, or to reduce alkali and metal chloride emissions. (IPPC (2000))

In this project we neglect the wastes to landfill because:

- their amount is not known (but small)
- their composition is not known
- their impact is well below the uncertainty of the impact of the air emissions

### **5.3.4 Transports**

Sinter usually is produced near the blast furnace while pellets are produced near the beneficiation plant. This is because pellets are made of fraction of the ore so fine that it would ask for elaborate technologies for transportation (especially loading and unloading).

Masses for transportation of the ore to the sinter plant and of the lump ore and pellets to the blast furnace are estimated according to the supply and demand situation in the different regions of the world. It is assumed, that as much ore as possible is used within these regions. Thus Western Europe and Asia are net importers while Eastern Europe / GUS, South America, Australia and Africa are net exporters. North America produces almost exactly as much iron ore as it consumes. An export mix is generated according to the export capacity of the net exporters and it is assumed that the imports of the net importers correspond to this mix. Distances within the regions are neglected and those between the regions and the means of transpiration are assumed. Data are given in Tab. 5.2.

Tab. 5.2 Transport masses and distances for iron ore and pellets

| Region           | Iron ore production 1995 |            | Pig iron production 1995 |            | Ore needed for pig iron production 1995 |            | Import demand total | Export composition |

### 5.3.5 Sinter and pellet production in ecoinvent

The background information to the processes are given in Tab. 5.3, flows are shown in:

- sinter, iron, at plant Fig. 5.6

- pellets, iron, at plant Fig. 5.7

Where (IPPC (2000)) is given as the source, arithmetic means of the low and high values are used in this project.

No data on the infrastructure are available. Thus the aluminium oxide plant (calcination plant) was chosen to represent the sinter and the pelletising plant.

**Tab. 5.3 Meta information for the iron ore agglomeration processes**

### Data quality

Data uncertainty is derived using the Pedigree matrix as described in (Frischknecht et al. (2003)) except for the infrastructure where this method would result in values far too low.

Data of input and main output materials for sintering and pelletising are of good overall quality.

Emission data for pelletising stem from all 5 pelletising plants in Europe. These 5 plants produced about 15 Mt of the 35 Mt pellets used in Europe in 1995. Thus data for European consumption are of rather high uncertainty.

Emission data for sintering stem from 5 of the 47 sinter plants in Europe. Thus data for European consumption are of rather high uncertainty.

A rough proxy is used for the infrastructure.

## 5.4 Blast furnace process: pig iron / hot metal production

This part is mainly based on Roth et al. (1999) and IPPC (2000).

### 5.4.1 Production process and infrastructure

The blast furnace remains by far the most important process for the production of pig iron. The technique is likely to continue to dominate pig iron production for at least the next 20 years.

A blast furnace is a closed system into which iron bearing materials (iron ore lump, sinter and/or pellets), additives (slag formers such as limestone) and reducing agents (coke) are continuously fed from the top of the furnace shaft through a charging system that prevents escape of blast furnace gas (BF gas). Fig. 5.8 shows a simplified layout of a blast furnace consisting of the furnace itself, the cast house, the hot stoves and two-stage treatment of BF gas.

Fig. 5.8 Simplified scheme of a blast furnace (IPPC (2000))

No data have been found on the infrastructure needed for the process. Assumptions made in this project are based on different pictures and information on the aluminium production infrastructure (see Tab. 5.4).

The infrastructure is modelled to be used for 50 years. The replacement of the machines with a life-time of only 25 years is taken into account by doubling the amount. Thus the values given in Tab. 5.5 are inventoried. For the waste disposal it is assumed that the conveyer belts and the machines are completely recycled. The disposal of the buildings is already inventoried in the building modules. Thus only the concrete and the refractory materials are disposed.

Tab. 5.4 Assumptions for infrastructure of blast furnaces

| blast furnace                                         | amount        | unit           | lifetime [a] | Material / Module          |

By-products of the pig iron production in blast furnaces are:

- Slag that is used in road building, concrete aggregate, thermal insulation (mineral wool) and as a cement replacement. Total utilisation of blast furnace slag is a target which has already been met in many cases.
- BF gas that contains about 20-28% CO, 1–5% H<sub>2</sub>, inert compounds (50-55% N<sub>2</sub>, 17-25% CO<sub>2</sub>), some sulphur and cyanide compounds and large amounts of dust from the burden. After treatment and enrichment, BF gas can be used in the hot blast stove or e.g. in the sinter production.
- Electricity recovered of the top gas pressure energy. Many plants with adequate top gas pressure (> 1.5 bar gauge) and sufficient pressure drop are suitable for installation of expansion turbines.

## 5.4.2 Emissions

### Air

Relevant direct air emissions from the pig iron production are CO, CO<sub>2</sub>, nitrogen oxides, sulphur oxides and heavy metals. The casting is responsible for most of the direct dust emissions.

CO<sub>2</sub> emission given in IPPC (2000) are considerably lower than the calculated C-balance suggests (Tab. 5.6). The calculated value from the C-balance (0.849 kg/kg) is used in ecoinvent v2.0 Data.

**Tab. 5.6 C-balance of blast furnace process**

## Water

There are no relevant direct water emissions from these processes

## 5.4.3 Waste

### Solid waste

Several different waste streams are generated. Some of them are recycled or used for different purposes and thus not inventoried. Others can not be used due to a high contamination and are deposited in landfills.

The sludge from BF gas treatment can't be reused because the zinc and lead compounds are mainly separated in the scrubber thus leading to a high contamination of the sludge. Sludge composition data are average data from IPPC (2000). The difference to 100 % is assumed to be water. (see Tab. 5.7).

There is no representative information available on the fate of the rubble waste/by-product. In some steelworks it is partly recycled to the BOF or reused for the production of new refractory material. In other cases it is put to landfill.

**Tab. 5.7 Typical composition in [% (w/w)] of sludge from BF gas treatment (IPPC (2000), Tab. 7.6)**

### Waste water

Overflow of water from slag granulation primarily depends on water availability and is in the range 0.125 – 10 m<sup>3</sup>/t pig iron produced. Information on chemical composition from one German plant is given in Tab. 5.8 (IPPC (2000), Tab 7.8).

**Tab. 5.8 Waste water composition from pig iron production (IPPC (2000), Tab 7.8)**

| Parameter | Unit                | Number of measurements | Average concentration | Median concentration | Emission factor | Unit                |
|-----------|---------------------|------------------------|-----------------------|----------------------|-----------------|---------------------|
| Flow      | [m <sup>3</sup> /d] |                        | 16000                 |                      | 1.96            | [m <sup>3</sup> /t] |
| Pb        | [µg/l]              | 19                     | 3.45                  | 2.0                  | 3.92            | [mg/t pig iron]     |

Emission factor is based on the median

### 5.4.4 Pig iron / hot metal in ecoinvent

The background information to the processes is given in Tab. 5.9, flows are shown in:

- pig iron, at plant Fig. 5.9
- blast furnace Fig. 5.10

Where (IPPC (2000)) is given as the source, arithmetic means of the low and high values are used in this project.

Transport distances for iron ore and pellets are shown in Tab. 5.2.

## Data quality

Data uncertainty is derived using the Pedigree matrix as described in Frischknecht et al. (2003) except for the infrastructure where this method would result in values far too low.

Data of input and main output materials for pig iron production are of good overall quality.

Emission data for pig iron production stem from 4 of 81 blast furnaces in Europe. Thus data for European consumption are of rather high uncertainty.

Data for the infrastructure is roughly estimated.

**Tab. 5.9 Meta information for the blast furnace processes**

Fig. 5.10 Flows for "blast furnace" and its representation in the ecoinvent database (cont.)

## 5.5 Making available of iron scrap

About 35% of the cast iron and steel production is based on scrap as iron source. While in the BOF converter scrap is only used to control the temperature of the melt, it is the only (or at least main) iron bearing input in the electric arc furnace.

A wide variety of iron scrap is processed in the secondary iron and steel industry. A basic differentiation is made between "new" and "old" scrap.

New scrap is surplus material that arises during production and fabrication of iron and steel products up to the point where they are sold to the final consumer. It is usually of known quality and alloy and often uncoated. Some new scrap is coated with paints or plastics.

Old scrap or post-consumer scrap is the iron and steel recovered after the product has been used by the final consumer. It comes into the secondary iron and steel industry via metal merchants and waste management companies which recover aluminium from e.g. vehicles, household goods etc. This is usually done by shredding, magnetic separation and "sink-and-float" installations or eddy current installations successively.

Because of the high process temperature and the addition of slag builder old and new scrap can be remelted with little preparation (no de-coating). No information on the share of the two types on the overall scrap market and on specific treatment or emissions from remelting of one or the other was found.

### 5.5.1 Iron scrap in ecoinvent

The background information to the processes are given in Tab. 5.10, flows are shown in Fig. 5.11.

#### Data quality

Data are based on rough assumptions and of poor quality.

Data uncertainty is not derived using the Pedigree matrix as described in (Frischknecht et al. (2003)) because the resulting values would seem to low.

## 5.6 Basic oxygen furnace (BOF) steel making

This part is mainly based on (IPPC (2000)).

The objective in oxygen steel making is to burn (i.e., oxidise) the undesirable impurities contained in the metallic feedstock. The main elements thus converted into oxides are carbon, silicon, manganese, phosphorus, and sulphur. The purpose of this oxidation process, therefore, is:

- to reduce the carbon content to a specified level (from approximately 4% to less than 1 %, but often lower)
- to adjust the contents of desirable foreign elements
- to remove undesirable impurities to the greatest possible extent

### 5.6.1 Production process and infrastructure

The production of steel by the BOF process is a discontinuous process which involves the following steps:

- transfer and storage of hot metal
- pre-treatment of hot metal (desulphurisation)
- oxidation in the BOF (decarburisation and oxidation of impurities)
- secondary metallurgical treatment
- casting (continuous or/and ingot)

The individual steps and their associated emissions are summarised in Fig. 5.12. More information on the individual steps is given in (IPPC (2000)).

Fig. 5.12 Individual steps in BOF steel making (IPPC (2000))

Desulphurisation can be done in the torpedo ladles used for transporting the hot metal from the blast furnace to the BOF. The most widespread hot metal desulphurisation method used in Europe today is

that based on calcium carbide, which has superseded the previous soda process for waste disposal and air quality management reasons.

There are several types of reactors used for the basic oxygen steel making process. The most commonly used type is the LD converter (Linz-Donawitz) applied for pig iron with low phosphorous content; in the case of high phosphorous content a modified process is used (LD/AC process = Linz-Donawitz/Arbed-CRM-process). The converter is a pear-shaped, refractory-lined reactor into which a water-cooled oxygen lance is lowered. Through this lance pure oxygen (>99%) from an air separation plant is blown onto the liquid pig iron. The amount of oxygen consumed depends on the composition of the hot metal (i.e. C, Si, P content). Thus undesired impurities are oxidised with subsequent removal with the off-gas or slag in the BOF furnace. The energy required to raise the temperature and melt the input materials is supplied by the exothermic oxidation reactions, so that no additional heat input is required, on the one hand, and scrap or ore have to be added to balance heat on the other hand. Usually, approximately 10-20% of the converter charge is scrap, but values up to 40% are sometimes used. The amount of scrap charged depends on the pre-treatment given to the pig iron and the required liquid steel tapping temperature. Variations in the market value of scrap and the required steel specifications also have an influence.

The oxidising process in the converter is usually followed by post-treatment comprising a number of metallurgical operations referred to as "secondary metallurgy". The main objectives of secondary metallurgy are:

- mixing and homogenising
- adjustment of chemical compositions to close analysis tolerances
- temperature adjustment in time for the downstream casting process
- deoxidisation
- removal of undesirable gases such as hydrogen and nitrogen
- improvement of the oxidic purity by separating non-metallic inclusions.

An overview of secondary metallurgy operations is given in (IPPC (2000)).

Once the final steel quality has been achieved the steel is conveyed in a casting ladle to the casting machines. Today, the method of choice (>95% in Europe) is continuous casting, whereby the steel is cast in a continuous strand.

No data have been found on the infrastructure needed for the process. Assumptions made in this project are based on different pictures and information on the aluminium production infrastructure (see Tab. 5.11).

**Tab. 5.11 Assumptions for infrastructure of BOF converters**

| <b>blast oxygen furnace converter</b>       | <b>amount</b> | <b>unit</b>    | <b>lifetime [a]</b> | <b>Material / Module</b>   |
|---------------------------------------------|---------------|----------------|---------------------|----------------------------|
| yearly production capacity (5000h; 300 t/h) | 1'500'000'000 | kg             | 50                  | Yearly production capacity |
| area of plant (500 x 100 m)                 | 500'000       | m <sup>2</sup> | 50                  | Transformed area           |
| administration building (20x10x10 m3)       | 2'000         | m <sup>3</sup> | 50                  | Building, multi story      |
| production hall (70% of total area)         | 400'000       | m <sup>2</sup> | 50                  | Building, hall             |
| torpedo ladle (without lining)              | 30'000        | kg             | 10                  | heavy machine, unspecific  |
| furnace & ladle                             | 1'000'000     | kg             | 25                  | heavy machine, unspecific  |
| lining for furnace & ladle                  | 100'000       | kg             | 25                  | firebrick                  |
| casting machines                            | 10'000'000    | kg             | 25                  | heavy machine, unspecific  |

The infrastructure is modelled to be used for 50 years. The replacement of the machines with a life-time of only 25 years is taken into account by doubling the amount, the amount of torpedo ladles is inventoried five times. The infrastructure is disposed after its useful life in inert material landfills. Thus the values given in Tab. 5.12 are inventoried. For the waste disposal it is assumed that the conveyer belts and the machines are completely recycled. The disposal of the buildings is already inventoried in the building modules. Thus only the concrete and the refractory materials are disposed.

**Tab. 5.12 Infrastructure of BOF converters**

## 5.6.2 Emissions

### Air

The gases produced during oxygen blowing (converter gas) contain large amounts of carbon monoxide. In many steel making plants, measures have been taken to recover the converter gas and use it as an energy source. Both "open combustion" and "suppressed combustion" systems are in use. Open combustion systems introduce air into the converter flue gas duct, thus combusting the carbon monoxide. The heat generated is later recovered in a waste heat boiler. In suppressed combustion, a skirt is lowered over the converter mouth during oxygen blowing. Thus, ambient oxygen can not enter the flue gas duct and the combustion of carbon monoxide is prevented. The CO-rich flue gas can be collected, cleaned and stored for subsequent use as fuel. A main advantage of suppressed combustion is the smaller flue gas flow since no combustion occurs and no additional air-nitrogen is introduced. This results in higher productivity since oxygen blowing speed can be increased.

The oxygen steel making process also generates considerable quantities of particulate matter, during charging of scrap and hot metal, blowing and during tapping of slag and liquid steel. All steel making shops in the EU have taken measures to reduce particulate matter emissions. The overall emissions given are in the lowest range in (Berdowski et al. (1995)) thus all particles are assumed to be below 2.5 µm.

### Water

There are no reports of direct water emissions from these processes.

## 5.6.3 Waste

During the steel making process, slag is formed. Slag control is intended to effectively reduce the amount of undesirable substances contained in the hot metal and to generate slag of high quality that will be suitable for subsequent processing and usage. Usually, the slag is cooled and crushed, after which metallic iron is recovered by magnetic separation. The technical properties of the slag make it suitable for many kinds of application in civil and hydraulic engineering. Because of its structure, LD

slag has high abrasion resistance and is therefore often used for road construction. It is also put to other uses or disposed of in landfills.

Desulphurisation slag is a heterogeneous slag which is only partially melted. The composition of desulphurisation slag strongly depends on the used desulphurisation agents. The typical composition of such a slag are given in Tab. 5.13.

**Tab. 5.13 Chemical composition of slag from pig iron desulphurisation [% (w/w)] (IPPC (2000), Tab.8.3)**

| CaO  | SiO <sub>2</sub> | Al <sub>2</sub> O <sub>3</sub> | MgO | Total Fe | Metallic Fe | MnO   | P <sub>2</sub> O <sub>5</sub> | Cr <sub>2</sub> O <sub>3</sub> | Free CaO | S   | CaO/SiO <sub>2</sub> |
|------|------------------|--------------------------------|-----|----------|-------------|-------|-------------------------------|--------------------------------|----------|-----|----------------------|
| 27.0 | 18               | 8                              | 10  | 20       | 15          | ≤ 0.5 | ≤ 0.2                         | ≤ 0.1                          | ≤ 5      | ≤ 4 | 1.5                  |

In this project ≤ x is interpreted as x/2

The relatively high sulphur content and unsatisfactory mechanical properties do not make desulphurisation slag ideal for reuse. Partly they are used for landfill construction or for noise protection barriers. In Europe 41% is landfilled.

The slag from basic oxygen steel making makes up the largest share of residues from BOF steel making. The chemical composition of this slag depends on the processes employed (see Tab. 5.14).

BOF slag can be reused by returning it to the iron-making process. It can also be used for fertiliser manufacture or for road construction. Lime phosphate slag (from LD/AC or OBM processes) is used entirely for fertiliser production. BOF slag is normally used in civil and hydraulic engineering, road construction and cement industry. Thereby the relatively high free CaO content has to be considered. Nevertheless, in the EU a considerable percentage (26%) of BOF slag is still put to landfill. For the composition of BOF slag used in this project see Tab. 5.14. Katz & Salem (1994) give a chromium content for steel mill slag of 100-200 ppm and 9'000-48'000 ppm. This indicates a rather wide range in which the value used in this project is included.

**Tab. 5.14 Chemical composition of BOF slag [% (w/w)] (IPPC (2000), Tab.8.8)**

| Process                        | LD/AC | LD   | AOD   | This project |
|--------------------------------|-------|------|-------|--------------|
| CaO                            | 50.0  | 50.0 | 53.0  | 51           |
| SiO <sub>2</sub>               | 9.0   | 15.0 | 28.0  | 16           |
| Al <sub>2</sub> O <sub>3</sub> | ≤ 2   | ≤ 2  | 3.0   | 1.6          |
| MgO                            | ≤ 3   | ≤ 3  | 5.0   | 2.6          |

| MnO                            | 2.0   | ≤ 4  | ≤ 1   | 1.5          |
| P <sub>2</sub> O <sub>5</sub>  | 15.0  | ≤ 2  | ≤ 0.5 | 8.7          |
| Cr <sub>2</sub> O <sub>3</sub> | ≤ 1   | ≤ 1  | ≤ 2   | 0.66         |
| Free CaO                       | ≤ 7   | ≤ 10 | ≤ 5   | 3.3          |
| S                              | -     | -    | ≤ 1   | 0.16         |
| CaO/SiO <sub>2</sub>           | 4     | 2.5  | 1.8   | 3.1          |

Legend: LD/AC = Linz-Donawitz/Arbed-CRM process; LD = Linz-Donawitz process;  
AOD = Argon-Oxygen-Decarburisation

This project = 0.57 \* LD/AC + 0.11 \* LD + 0.32 \* AOD based on capacity in Europe (IPPC (2000), Tab.8.1) with ≤ x interpreted as x/2

Coarse dust waste is usually reused while fine dust, due to high Pb and Zn contamination is partly landfilled. About 60% of the total dust waste is fine dust of which 42% is landfilled (IPPC (2000), Tab.8.6, Fig. 8.15). Thus it is assumed that 25% of the total dust is landfilled. The composition of this dust is assumed according to the information for fine dust of one plant given in Tab. 5.15. The composition of this dust seems rather incomplete. Especially the lack of Cr and Ni in the dust also for stainless steel probably is due to these elements not being measured. Considering the high environmental relevance of these elements in landfills, this data gap would lead to considerable underestimation of environmental effects. Data for the electric arc furnace (EAF) dusts are much more comprehensible (cf. Tab. 5.21). For this reason, the disposal modules of EAF dusts are inventoried as proxy for the disposal of the BOF dust.

**Tab. 5.15 Chemical composition of the BOF dust fraction that is landfilled [% (w/w)]. Data not used in this project (cf text) (IPPC (2000), Tab.8.9)**

| Parameter   | Coarse dust | Fine dust   |
|-------------|-------------|-------------|
| Total Fe    | 30 – 85     | 54 – 70     |
| Metallic Fe | 72          | 20          |
| CaO         | 8 – 21      | 3 – 11      |
| Zn          | 0.01 – 0.4  | 1.4 – 3.2   |
| Pb          | 0.01 – 0.04 | 0.2 – 1.0   |
| S           | 0.02 – 0.06 | 0.07 – 0.12 |
| C           | 1.4         | 0.7         |

#### 5.6.4 Converter steel in ecoinvent

The background information to the processes is given in Tab. 5.17, flows are shown in:

- steel, converter, unalloyed, at plant Fig. 5.13
- steel, converter, low-alloyed, at plant Fig. 5.14
- steel, converter, chromium steel 18/8, at plant Fig. 5.15
- blast oxygen furnace converter Fig. 5.16

If not stated otherwise, arithmetic means of the low and high values given in (IPPC (2000)) are used in this project.

Because the different slag fractions of the BOF process that are not recycled or reused can be assumed to be landfilled together, these wastes are treated as one having an average composition according to Tab. 5.16.

**Tab. 5.16 Chemical composition of the average BOF slag to landfill [% (w/w)]**

|                                | desulphurisation slag | BOF slag | BOF slag, average |
|--------------------------------|-----------------------|----------|-------------------|
| CaO                            | 27                    | 51       | 48.3              |
| SiO <sub>2</sub>               | 18                    | 16       | 16.5              |
| Al <sub>2</sub> O <sub>3</sub> | 8                     | 1.6      | 2.51              |
| MgO                            | 10                    | 2.6      | 3.66              |
| Total Fe                       | 20                    | 8.9      | 10.5              |
| Metallic Fe                    | 15                    | 0.5      | 2.51              |
| MnO                            | 0.25                  | 1.5      | 1.35              |
| P <sub>2</sub> O <sub>5</sub>  | 0.1                   | 8.7      | 7.62              |
| Cr <sub>2</sub> O <sub>3</sub> | 0.05                  | 0.66     | 0.584             |
| Free CaO                       | 0.25                  | 3.3      | 2.92              |
| S                              | 2                     | 0.16     | 0.417             |
| CaO/SiO <sub>2</sub>           | 1.5                   | 3.1      | 2.92              |

BOF waste, average = 0.14 \* desulphurisation slag + 0.86 \* BOF slag (according to amount to landfill),  
linear extrapolation to 100% (from 102%)

For the elemental composition, CaOSiO<sub>2</sub> is interpreted as 50% CaO and 50% SiO<sub>2</sub>

### Data quality

Data uncertainty is derived using the Pedigree matrix as described in (Frischknecht et al. (2003)) except for the infrastructure where this method would result in values far too low.

Data of input and main output materials as well as emission data for BOF steel production stem from 4 of 95 basic oxygen furnaces in Europe. Thus data for European consumption are of rather high uncertainty.

Data for the infrastructure is roughly estimated.

Tab. 5.17 Meta information for the BOF steel production processes

## 5.7 Electric arc furnace (EAF) steel making

This part is mainly based on (IPPC (2000)).

The direct smelting of iron-containing materials, such as scrap is usually performed in electric arc furnaces (EAF) which play an important and increasing role in modern steel works concepts. Today the percentage of electric arc furnace steel of the overall steel production in the EU is 35.3 %.

The major feed stock for the EAF is ferrous scrap, which may comprise of scrap from inside the steel-works, cut-offs from steel product manufacturers (e.g. vehicle builders) and capital or post-consumer scrap (e.g. end of life products). Direct-reduced iron (DRI) is also increasingly being used as a feed-stock due both to its low gangue content and variable scrap prices. As in the BOF, a slag is formed from lime to collect undesirable components in the steel.

### 5.7.1 Production process and infrastructure

The production of steel by the EAF process is a discontinuous process which involves the following steps:

- raw material handling and storage
- furnace charging with/without scrap preheating
- EAF scrap melting
- steel and slag tapping
- ladle furnace treatments for quality adjustment
- slag handling
- continuous casting

For high alloyed and special steels (15% of European steel production), the operation sequence is more complex and tailor-made for the end-products. In addition to the mentioned operations for carbon steels various ladle treatments (secondary metallurgy) are carried out like

- desulphurisation
- degassing for the elimination of dissolved gases like nitrogen and hydrogen
- decarburisation (AOD=Argon-Oxygen-Decarburisation or VOD=Vacuum-Oxygen-Decarburisation)

The actual melting is done by lowering graphite electrodes to the scrap until they strike an arc that melts the scrap. More information on the individual steps is given in (IPPC (2000)).

No data have been found on the infrastructure needed for the process. Assumptions made in this project are based on different pictures and information on the aluminium production infrastructure (see Tab. 5.18).

**Tab. 5.18 Assumptions for infrastructure of EAF converters**

| electric arc furnace converter                     | amount      | unit           | lifetime [a] | Material / Module          |
|----------------------------------------------------|-------------|----------------|--------------|----------------------------|
| yearly production capacity (5000h; 100 t/h)        | 500'000'000 | kg             | 50           | Yearly production capacity |
| area of plant (500 x 100 m)                        | 500'000     | m <sup>2</sup> | 50           | Transformed area           |
| administration building (50x50x10 m <sup>3</sup> ) | 2'000       | m <sup>3</sup> | 50           | Building, multi story      |
| production hall (50% of total area)                | 250'000     | m <sup>2</sup> | 50           | Building, hall             |
| furnace & ladle                                    | 500'000     | kg             | 25           | heavy machine, unspecific  |
| lining for furnace & ladle                         | 50'000      | kg             | 25           | firebrick                  |
| casting machines                                   | 5'000'000   | kg             | 25           | heavy machine, unspecific  |

The infrastructure is modelled to be used for 50 years. The replacement of the machines with a lifetime of only 25 years is taken into account by doubling the amount. The infrastructure is disposed after its useful life in inert material landfills. Thus the values given in Tab. 5.21 are inventoried. For the waste disposal it is assumed that the conveyer belts and the machines are completely recycled. The disposal of the buildings is already inventoried in the building modules. Thus only the concrete and the refractory materials are disposed.

**Tab. 5.19 Infrastructure of EAF converters**

|                                         | electric arc furnace converter | Unit           | Remarks                 |

## 5.7.2 Emissions

### Air

Relevant emissions of heavy metals varying largely with the scrap quality occur in electric steel making. Also varying with the scrap quality are chlorinated hydrocarbon emissions such as PCB and dioxins. Other VOC emissions can be remarkably high and correspond with the use of coal.

The overall particle emissions given are in the medium range in (Berdowski et al. (1995)) thus 42.5% of particles are assumed to be smaller than 2.5 µm, 42.5% of particles are assumed to be between 2.5 µm and 10 µm and 15% of particles are assumed to be larger than 10 µm.

### Water

Drainage water from unpaved scrap-yards can be contaminated, especially in case of oil/emulsion containing scrap like turnings. There is no information available on quantities and pollution of drainage water. Usually it is at least treated in an oil separator prior to be discharged.

### Soil

Soil contamination may arise from contaminated scrap in scrap-yards. No information on quantities and pollutants is available.

### 5.7.3 Waste

The main waste generated in EAF steel making is slag. Their composition slightly depends on the alloy and on the sub-process they are generated in. The differences are not significant and therefore neglected in this study. One average composition is established (see Tab. 5.20). The recycling fraction also depends on the alloy. While slag from carbon steel and low alloyed steel production are landfilled to 69% and 59% respectively, only 53% of the slag from high alloyed steel production is landfilled.

Tab. 5.20 Chemical composition of slag from EAF steel making [% (w/w)]

| CaO               | SiO <sub>2</sub> | Al <sub>2</sub> O <sub>3</sub> | MgO   | Total Fe | TiO <sub>2</sub> | MnO | P <sub>2</sub> O <sub>5</sub> | Cr <sub>2</sub> O <sub>3</sub> | Free CaO | S     | C    |
|-------------------|------------------|--------------------------------|-------|----------|------------------|-----|-------------------------------|--------------------------------|----------|-------|------|

| Na <sub>2</sub> O | K <sub>2</sub> O | V <sub>2</sub> O <sub>5</sub>  | ZnO   | CuO      | NiO              |     |                               |                                |          |       |      |
| 0.47              | 0.11             | 0.18                           | 0.021 | 0.031    | 0.21             |     |                               |                                |          |       |      |

Arithmetic mean of values in (IPPC (2000), Tab. 9.4), linear adjusted to 100% (from 97.5%). In this project  $\leq x$  is interpreted as  $x/2$

As already mentioned the treatment of off gases (mostly primary off gases together with secondary off gases) is very often performed in bag filters. The composition of dusts from production of carbon, low alloyed and high alloyed steel can be seen from Tab. 5.21.

Wastewater also results from off gas treatment in a wet scrubber and from direct cooling from continuous casting. For the former wastewater no information on applied treatment techniques and discharged quantities and its pollution is available. Latter wastewater contains mill scale (1–3 g/l) and oil/grease. Usually this wastewater is treated together with other streams from the rolling mills.

Tab. 5.21 Chemical composition of dust from EAF steel making [% (w/w)]

| Component                      | Dust from carbon/low-alloyed steel production | Dust from high-alloyed / stainless steel production | Dust from carbon/low-alloyed EAF steel in this project | Dust from high-alloyed EAF steel in this project |
|--------------------------------|-----------------------------------------------|-----------------------------------------------------|--------------------------------------------------------|--------------------------------------------------|

This project = arithmetic mean values, linear adjusted to 100% (from 104% and 108% for carbon/low-alloyed steel and high-alloyed steel respectively)

#### 5.7.4 Electric steel in ecoinvent

The background information to the processes are given in Tab. 5.22, flows are shown in:

- steel, electric, un- and low-alloyed, at plant Fig. 5.17
- steel, electric, chromium steel 18/8, at plant Fig. 5.18
- electric arc furnace converter Fig. 5.19

If not stated otherwise, arithmetic means of the low and high values given in (IPPC (2000)) are used in this project.

Tab. 5.22 Meta information for the EAF steel production processes

### Data quality

Data uncertainty is derived using the Pedigree matrix as described in (Frischknecht et al. (2003)) except for the infrastructure where this method would result in values far too low.

Data of input and main output materials as well as emission data for EAF steel production stem from an unknown number of 203 electric arc furnaces in Europe. Thus data for European consumption are of rather high uncertainty.

Data for the infrastructure is roughly estimated.

## 5.8 Cast iron

### 5.8.1 Production process and infrastructure

Cast iron is made by remelting pig iron in small furnaces (e.g. cupola furnaces or electric arc furnaces) and poured into moulds to make castings. It usually contains 2% to 6% carbon. Scrap iron or steel is often added to vary the composition. Cast iron is used extensively to make machine parts, engine cylinder blocks, stoves, pipes, steam radiators, and many other products. Grey cast iron, or grey iron, is produced when the iron in the mould is cooled slowly. Part of the carbon separates out in plates in the form of graphite but remains physically mixed in the iron. Grey iron is brittle but soft and easily machined. White cast iron, or white iron, which is harder and more brittle, is made by cooling the molten iron rapidly. The carbon remains distributed throughout the iron as cementite (iron carbide,  $\text{Fe}_3\text{C}$ ). A malleable cast iron can be made by annealing white iron castings in a special furnace. Some of the carbon separates from the cementite; it is much more finely divided than in grey iron. A ductile iron may be prepared by adding magnesium to the molten pig iron; when the iron is cast the carbon forms tiny spherical nodules around the magnesium. Ductile iron is strong, shock resistant, and easily machined.<sup>7</sup>

### 5.8.2 Emissions

#### Air

Air emissions depend mainly on the type of furnaces and the fuel used in them. Emission composition of the production in a cupola furnace is similar to that of the blast furnace while emissions of the cast iron production in electric arc furnaces is similar to those of the steel making in those furnaces.

#### Water

There are no reports of direct water emissions from these processes.

### 5.8.3 Waste

As for the steel making the main wastes from cast iron production is slag and filter dust. No specific information was found.

### 5.8.4 Cast iron in ecoinvent

The background information to the process "cast iron, at plant" are given in Tab. 5.23, and flows are shown in Fig. 5.20

For a lack of specific data the cast iron production is inventoried using the data of the EAF steel making but assuming a mix of iron input of 65% pig iron and 35% scrap. Since cast iron usually is un- or low-alloyed and melted in electric furnaces, this assumptions seem justified.

**Data quality**

Data uncertainty is derived using the Pedigree matrix as described in (Frischknecht et al. (2003)) except for the infrastructure where this method would result in values far too low.

Data are estimates based on a technology that is similar to one of different technologies used in the cast iron production. Thus data uncertainty is rather high.

Data for the infrastructure is roughly estimated.

## **5.9 Consumer mixes for carbon steel, low-alloy steel and stainless steel**

### **5.9.1 Steel in ecoinvent**

The different steel alloys inventoried in ecoinvent are modelled by mixtures of differently produced steel and alloy materials. In Europe in 2000 39.8% of the steel was produced in electric furnaces and the remaining 60.2% in basic oxygen furnaces. The world production mix was 58.5% basic oxygen furnace, 34% electric furnace and 4.4% open hearth furnace (IISI (2002)). For the consumption mix in Europe we assume 63% BOF and 37% EAF production.

Because steel for every application is hot rolled, this process is also included in the modules. For a description of the process see Part IXX Metalprocessing.

The background information to the processes is given in Tab. 5.24, and flows are shown in:

- reinforcing steel, at plant Fig. 5.21
- steel, low-alloyed, at plant Fig. 5.22
- chromium steel 18/8, at plant Fig. 5.23

### **Data quality**

Data uncertainty is derived using the Pedigree matrix as described in (Frischknecht et al. (2003)).

The shares of the different technologies stem from a statistical yearbook. Thus the data are reliable.

## Comments on version 2.1

This part corresponds to the original report in Althaus et al. (2004) that has been updated with the changes reported in Frischknecht et al. (2006). The changes were implemented with v1.2 and affect mainly the datasets for primary and secondary copper by increasing the emission factors to air for dioxin, carbon monoxide, particulate matter and volatile organic compounds.

The inventories covering copper alloys (brass, bronze and brazing solder), which were treated in the now removed “Part VIII Other Metals” in Althaus et al. (2004), are now included in this Part III.

Additionally the generation of telluride and silver containing anode slime has been introduced in this version to answer the related demand from the inventories of gold and silver (Part IX) and tellurium (Part X). This extension was part of the mandate commissioned by the Swiss Federal Office for the Environment (FOEN) to improve the overall quality and applicability of the metals inventories.

In version 2.1 we corrected an error in the dataset “molybdenum, at regional storage (RER)”. See Fig. 5.21.

Chapter “6 Cumulative Results and Interpretation” of the original report has been deleted for the current update.

## Summary

The primary copper and molybdenum production is modelled for the global situation, based on data from various sources. Additionally, the situations for different concentrate-producing regions are modelled separately. Since most of tellurium and considerable parts of silver originate from copper production, a specific chapter treats the generation of silver and telluride containing anode slime.

The mining and beneficiation are modelled as coupled processes with copper and molybdenite concentrate as outputs.

For copper also the secondary production in Europe is inventoried. Finally a mix is generated to be used for copper consumed in Europe.

Some of the datasets described in this report make only sense in the context of the copper and molybdenum production and are therefore not intended for other uses.

The datasets to be chosen to represent copper in a LCA study are either one of the primary copper datasets, the secondary copper dataset or the European mix (at regional storage). The decision whether to use primary, secondary or a mix of the two depends on the goal and scope of the LCA to be conducted.

If molybdenum is needed as alloying element in an LCA study, molybdenite should be chosen as input. The metallic molybdenum is only used in very specific applications.

# 1 Introduction

This chapter describes the production of copper from mining of the ore to consumer in Europe and the coupled production of molybdenum. Inventory data for the copper production is taken mainly from Krauss et al. (1999) together with background data from IPPC (2002), IPPC (2001), EEA (1999) and Ayres et al. (2002) (primary copper) and Rentz et al. (1999) and Bruch et al. (1995) (secondary copper).

Since copper is always associated with other metals, the production yields a fraction of other metals than copper, mainly nickel (Ni), molybdenum (Mo) and platinum group metals. The process of primary production described in this chapter is formally a multioutput-process with the coupled products Cu and Mo. No other potential co-products have been considered in this study. This makes it necessary to allocate the inventory to these products. The demand for copper-containing ore is allocated by mass. The rest of the inventory is allocated by revenue.

Copper is used as pure metal and as alloying element with other metals and in steels. On the other hand, molybdenum is almost exclusively used as alloying element in steels. Its marketed product form is molybdenum trioxide and ferromolybdenum.

According to EEA (1999), emissions of sulphur dioxide from non-ferrous metal production, particularly copper production, contribute less than 10% to the total global emissions of this pollutant. However, copper smelting can be the most important source of sulphur dioxide emissions in certain regions, such as the Kola Peninsula, the Urals, the Norilsk area, and the Fergana region in Russia, Lower Silesia in Poland, and the Gijon region in Spain. During the copper production process various trace elements originating from impurities in the ore are emitted to the atmosphere. This process is the major source of atmospheric arsenic and copper (about 50 % of the global emissions of the element), and indium (almost 90 %), and a significant source of atmospheric antimony, cadmium and selenium (ca. 30 %), and nickel and tin (ca. 10 %). The production of copper together with nickel is the major source of pollution from these and other elements in regions with non-ferrous metal production.

According to mythology, the goddess Venus (or Aphrodite) was born on the Mediterranean island of Cyprus, formerly Kypros (Greek), where copper was exploited millennia before Christ. Therefore, in early times the Romans named it cyprium, later called cuprum. This name is the origin of copper and of the corresponding words in most Romance and Germanic languages, e.g., cobre (Spanish and Portuguese), cuivre (French), Kupfer (German), koper (Dutch), and koppar (Swedish).

## 2 Reserves and Resources of Copper and Molybdenum

Metals are a special class of materials. They are not consumed but rather used during a product life cycle. When recovered the properties are theoretically identical to those in the raw material. The metal can be re-used in another product life cycle, provided that its concentration makes a recovery economic. The recovered metal is referred to as secondary metal, whereas the metal originating directly from the ore is referred to as primary metal. In LCIs these two types – primary and secondary metal – are often differentiated because they are assigned with different ecological burden.

Molybdenum and Copper are coexisting in porphyry deposits of the copper-molybdenum type, as molybdenite ( $\text{MoS}_2$ ) and chalcopyrite ( $\text{CuFeS}_2$ ). About half of the world-wide produced molybdenum is a co-product of the primary copper industry while for another substantial part copper is the co-product (Krauss et al. (1999) and Sebenik et al. (1997)). Hence almost all of the molybdenum is produced in a process similar to the copper primary production. Molybdenum secondary production – mainly from spent petroleum catalysts – is not remarkable, and no secondary production is considered in this study. USGS (2003) estimates that 30% of the molybdenum is re-used in the form of the molybdenum content steel alloys which are recycled to the foundries. Secondary production of copper from scrap plays an important role. The resources of primary copper are limited, a continuous depletion within 60 years is estimated (Ayres et al. (2002), p. 10).

### 2.1 Primary copper

Recoverable copper deposits are now mostly (90-95%) in the form of disseminated sulphide minerals, such as chalcopyrite ( $\text{CuFeS}_2$ ), chalcocite ( $\text{Cu}_2\text{S}$ ), bornite ( $\text{Cu}_5\text{FeS}_4$ ) and enargite ( $\text{Cu}_3\text{AsS}_4$ ). On average, a tonne of sulphur is associated with each tonne of copper. By far the most important deposits are of the disseminated porphyry copper type, in which the dominant mineral is chalcopyrite. Globally, 90%-95% of copper is derived from sulphide ores. Arsenic is associated with some porphyry copper deposits, such as Butte, Montana, and El Indio (Chile).

Another type of porphyry deposit is the copper-molybdenum type, in which the mineral molybdenite ( $\text{MoS}_2$ ) is interspersed with chalcopyrite, as in Henderson Colorado, Quartz Hill Canada and a few other locations in Chile and the Philippines. These ore bodies are mainly mined for molybdenum, with copper as a by-product.

So called oxide ores, which account for 5%-10% of global output, are weathered products of sulphide minerals, notably malachite ( $\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$ ), azurite ( $2\text{CuCO}_3 \cdot \text{Cu}(\text{OH})_2$ ), cuprite ( $\text{Cu}_2\text{O}$ ) and chrysocolla ( $\text{CuSiO}_3 \cdot 2\text{H}_2\text{O}$ ) (Ayres et al. (2002)).

Overall more than 200 minerals contain copper in definable amounts, but only ca. 20 are of importance as copper ores (Tab. 2.1) or as semiprecious stones (turquoise and malachite). Secondary minerals are formed in sulphide ore bodies near the earth's surface in two stages. In the oxidation zone, oxygen-containing water forms copper oxides, subsalts (subcarbonates and subsulphates), and silicates. In the deeper cementation zone, copper-bearing solutions from these salts are transformed into secondary copper sulphides (chalcocite and covellite) and even native copper of often high purity, e.g., in the Michigan copper district (Keweenaw Peninsula). The grade of copper ore at a mine or in a mining region decreases as ore is removed, sometimes dropping below that of gangue left from earlier mining. The grade of the copper ore mined and milled in the U.S. dropped from 3.5% in 1900 to nowadays under 0.7% which was the content of the 1900's tailings (Fig. 2.1, Graedel et al. (2002)).

Fig. 2.1 Development of copper ore grade in U. S. since 1880 (Ayres et al. (2002)).

Other metallic elements frequently found in copper ores are iron, lead, zinc, antimony, and arsenic; less common are selenium, tellurium, bismuth, silver, and gold. Substantial enrichments sometimes occur in complex ores. For example, ores from Sudbury, Ontario, in Canada contain nickel and copper in nearly the same concentrations, as well as considerable amounts of platinum metals. The copper ores from Zaire and Zambia are useful sources of cobalt. Many porphyry copper ores in America contain significant amounts of molybdenum and are the most important single source of rhenium. The extraction of precious metals and other rare elements can be decisive for the profitability of copper mines, smelters, and refineries (Fabian (1997)).

Land-based resources are estimated to be 1.6 billion tons of copper, and resources in deep-sea nodules are estimated to be 700 million tons (USGS (2003)). A detailed overview over the global refinery production and a statistic on US use and production of copper is available in the online version of the USGS “Mineral Commodity Summary” (USGS (2003)). The world-wide mine production by country in 2002 and the estimated reserves are listed in Tab. 2.3, copper production over the last seven thousand years is shown in Fig. 2.2.

Exploitable reserves of recoverable copper were estimated at about 100 million tons in 1935; new discoveries raised this to 212 million tons in 1960. Reserves grew again sharply to 340 million metric tons (MMT) in 1984, but since then they have declined slowly to 321 MMT in 1990 and 310 MMT in 1994. Estimates vary according to prices and assumptions. Total potential resources have increased somewhat over the same period, from 500 MMT to around 590 MMT. As a matter of interest, cumulative global production of copper between 1970 and 1996 was 216 MMT (Ayres et al. (2002), p. 10). According to USGS in 2002 (Tab. 2.3) estimated resources amount to 480 MMT (“reserves”) and potential resources to 950 MMT (“reserve base”). With the actual mine production of around 13.5 MMT/a, the reserves would last 36 years and the reserve base 70 years.

Production of tellurium and silver are tightly related to the production of copper. Tellurium occurs in tellurium-bearing minerals such as sylvanite ((Au, Ag)<sub>2</sub>Te<sub>2</sub>) in copper and gold deposits. Silver and tellurium are contained in small traces in the copper ore and arise in the anode slime of the electrolytic

refining of copper. Whereas tellurium is won almost exclusively as by-product from the copper production<sup>1</sup>, copper ores contribute to 25-30% to the world silver supply (Klapwijk et al. (2006)).

Tab. 2.1 Resources. The most important copper minerals (Fabian (1997)).

| Mineral       | Formula                                                                 | Copper wt-% | Crystal system | Density, g/cm <sup>3</sup> |
|---------------|-------------------------------------------------------------------------|-------------|----------------|----------------------------|
| Native copper | Cu                                                                      | 99.92       | Cubic          | 8.9                        |

Tab. 2.2 Occurrence. Typical copper contents of natural materials (Fabian (1997)).

| Mineral                 | Content (ppm) |
|-------------------------|---------------|
| Basalt                  | 85            |
| Diorite                 | 30            |
| Granite                 | 10            |
| Sandstone               | 1             |
| Copper ores (poor)      | 5'000         |
| Copper ores (rich)      | 50'000        |
| Native copper           | 950'000       |
| Seawater                | 0.003         |
| Deep-sea clays          | 200           |
| Manganese nodules       | 10'000        |
| Marine ore sludges      | 10'000        |
| Earth's crust (average) | 50            |
| Meteorites (average)    | 180           |

Tab. 2.3 Mine production and reserves of copper in 2001. "Reserves" is referred to as "the part of the reserve base which could be economically extracted or produced at the time of determination", while "Reserve base" denotes "that part of an identified resource that meets specified minimum (...) criteria related to current mining and production practices" (USGS (2003)).

|                              | Mine production  |                                 | Reserves | Reserve base |
|------------------------------|------------------|---------------------------------|----------|--------------|

Fig. 2.2 History of copper production in logarithmic scale (Ayres et al. (2002)).

## 2.2 Primary Molybdenum

About the half of the world-wide produced molybdenum originates as co-product from the copper industry. The chief mineral values for the coupled production of molybdenum and copper are chalcopyrite ( $\text{CuFeS}_2$ ) and chalcocite ( $\text{Cu}_2\text{S}$ ), associated with pyrite ( $\text{FeS}_2$ ), and small amounts of other sulphides, including molybdenite. Generally there are five genetic types of molybdenum deposits (Sebenik et al. (1997)):

1. porphyry deposits in which metallic sulphides are disseminated throughout large volumes of altered and fractured rock,
2. contact-metamorphic zones and bodies in which silicated limestone is adjacent to intrusive granites,
3. quartz veins,
4. pegmatites, and
5. deposits bedded in sedimentary rocks.

Types (1) – (3) are of hydrothermal origin and provide almost all of the molybdenum ore currently mined. The last two are of no economic importance at present. Average molybdenite concentrations in primary porphyry deposits range from 0.05 to 0.25 %; in secondary copper-molybdenum porphyry deposits molybdenite concentrations are much lower (0.01 – 0.05 %) so that the mineral can only be recovered as a by-product.

Molybdenum is obtained commercially almost exclusively from molybdenite, which is either mined and concentrated as the primary product of the mine or open pit, or recovered as a concentrate during the processing of ore from a copper mine. In the latter case the molybdenite can be either a by- or a co-product, depending on its economic importance to the output of the mine. Molybdenum is also recovered from solutions obtained by leaching scheelite ores in the production of tungsten. It is extracted as a by- or co-product of copper production in Canada, Chile, Iran, Mexico, Papua New Guinea, Peru, Philippines, and in the United States (Arizona, Nevada, New Mexico, and Utah).

Molybdenum supply in the Western world can be broken down into four production segments (Sebenik et al. (1997)):

- 1) primary mine production (ca. 40 %),
- 2) by- or co-production output from copper and scheelite mines (ca. 55 %),
- 3) imports from the People's Republic of China (3 %), and
- 4) molybdenum recovered from the processing of spent petroleum catalyst (2 %).

The world mine production of molybdenum amounted to 130 kt in 2001 (USGS (2003)).

Reserves of molybdenite in the market economy countries have been estimated in a survey evaluating identified ore bodies, i.e., those which have been explored as well as those which have been exploited. The results indicate the following amounts of recoverable molybdenum: United States, 4100 kt; Chile, 1770 kt; Canada, 928 kt; Mexico, 306 kt; Peru, 288 kt; other countries, 356 kt. Ore bodies producing primarily molybdenum contain 55 % of the reserves identified; only 29 % of these ore bodies were being exploited at the time of the survey (January 1985). Operations producing molybdenum as a by-product contained the remaining 45 % of reserves and 67 % of them were producing molybdenite (Sebenik et al. (1997)). The estimated total recoverable molybdenum from primary and byproduct reserves is listed in Tab. 2.5.

Tab. 2.5 Global reserves of molybdenum. Total recoverable reserves from primary production and as by-product (Sebenik et al. (1997)).

| Source of reserve                 | Amount in [kt] |
|-----------------------------------|----------------|
| Primary producing properties      | 1'265          |
| Primary nonproducing properties   | 3'036          |
| Byproduct producing properties    | 2'316          |
| Byproduct nonproducing properties | 1'142          |

## 2.3 Secondary Copper

The recycling of copper is as old as the usage of the metal itself. World-wide refinery production in year 2000 was  $14.9 \cdot 10^6$  tonnes copper, of which  $1.92 \cdot 10^6$  tonnes copper (=13.2%) originated from secondary copper sources (USGS (2003)). In Germany in 1994,  $1.48 \cdot 10^6$  tonnes copper was consumed, of which  $0.65 \cdot 10^6$  tonnes were from secondary materials, of which again roughly 50% was re-cycled in the metallurgical step (Krauss et al. (1999)).

Scrap is classified as prompt scrap (new scrap, manufacturing scrap), which is generated during the fabrication of copper products, and old scrap, which is generated from products exiting the use phase. These differ greatly in their quality. Because of its high purity, most of the prompt scrap can be directly re-melted, while a good deal of old scrap has to return to the refinery and the smelter stage. About 36% of the copper in old scrap comes from pure copper products, and about 64% from alloy products (Ayres et al. (2002)). Bertram et al. (2002) suggest to assume that the old scrap consists of the waste categories ELV, C&D, and WEEE (Tab. 2.6).

Depending on the quality of the recycled material, the blending of primary and secondary substance flows takes place at different production stages. In general, secondary copper used in smelters and refineries is composed of 70% old and 30% prompt scrap. For the year 1994 Bertram et al. (2002) calculated an input of 540 kt of old scrap and 230 kt (=29.9%) of prompt scrap into the smelters / refineries and an input of 200 kt of old scrap and 750 kt (=78.9%) of prompt scrap into the production of semis (semi-fabricated products, such as shapes and ingots).

Tab. 2.6 Sources of copper waste for Europe in 1994 (Bertram et al. (2002)).

| Source                                 | Total waste |               |      | Copper content |                        |           |                   |
|----------------------------------------|-------------|---------------|------|----------------|------------------------|-----------|-------------------|

## 3 Characterisation of the materials

### 3.1 Copper

Copper [7440-50-8], the red metal, apart from gold the only metallic element with a colour different from a grey tone, has been known since the early days of the human kind. It has always been one of the significant materials, and today it is the most frequently used heavy non-ferrous metal. The utility of pure copper is based on its physical and chemical properties, above all its electrical and thermal conductivity (exceeded only by silver), its outstanding ductility and thus excellent workability, and its corrosion resistance (a chemical behaviour making it a half-noble metal). Copper compounds and ores are distinguished by bright coloration, especially reds, greens, and blues. Copper in soil is an essential trace element for most creatures, including humans. Its common alloys, particularly brass and bronze, are of great practical importance. Commercial grades of cathode copper today range from 99.95% to 99.97% pure.

Most properties of metallic copper depend on the degree of purity and on the source of the metal. Variations in properties are caused by

- Grade of copper, i.e., the oxygen content: tough-pitch copper, deoxidised copper, oxygen-free copper;
- Content of native impurities (e.g., arsenic) or remnants of additives (e.g., phosphorus), which form solid solutions or separate phases at the grain boundaries;
- Thermal and mechanical pre-treatment of the metal, which lead to states such as cast copper, hot-rolled copper, cold-worked (hard) copper, annealed (soft) copper, and sintered copper.

The atomic number of copper is 29, and the atomic mass  $A_r$  is  $63.546 \pm 0.003$ . Copper consists of the two natural, stable isotopes  $^{63}\text{Cu}$  (68.94 %) and  $^{65}\text{Cu}$  (31.06 %). There are also nine synthetic radioactive isotopes with atomic masses between 58 and 68, of which  $^{67}\text{Cu}$  has the longest half-life, ca. 58.5 h.

The theoretical density at 20 °C, computed from lattice constant and atomic mass is  $8.93 \text{ g/cm}^3$ . The international standard was fixed at  $8.89 \text{ g/cm}^3$ . The density of commercial copper depends on its composition, especially the oxygen content, its mechanical and thermal pre-treatment, and the temperature. At 20 °C, a range of values from  $8.30 \text{ g/cm}^3$  to  $8.93 \text{ g/cm}^3$  are found.

The corresponding electrical resistivity ( $\rho$ ) is  $1.7241 \times 10^{-8} \text{ W}\cdot\text{cm}$ . The theoretical conductivity at 20 °C is nearly 60.0 MS/m or 103.4 % IACS, and today commercial oxygen-free copper (e.g., C10200 or Cu – OF) has a conductivity of 101 % IACS.

### 3.2 Copper alloys: brass bronze and brazing solders

This chapter is mainly based on Isbell (1997) and on a internet source<sup>2</sup>

There are scores of different copper alloys ranging from high copper alloys with copper content of >99% (w/w) to brasses with only about 50% (w/w) copper. A differentiation of wrought and cast copper alloys is common.

---

<sup>2</sup> <http://www.stahl-info.de/deutsch/schriften/MB235-WeichundHartloeten.pdf>, accessed on 16.04.03

### 3.2.1 Brass

The series of alloys from which a majority of the industry's products are made are the copper-zinc alloys – the brasses. The most popular alloy of the group is cartridge brass (70/30 brass). Zinc is by far the most important alloying element in the copper alloys. Lead can be alloyed to brasses to enhance the machinability. If secondary material is used to produce copper alloys, contamination with unwanted heavy metals (e.g. lead, cadmium, beryllium...) can be a problem.

### 3.2.2 Bronze

Also of technical relevance are the copper-tin alloys – the tin bronzes. Beside about 5% (w/w) (maximum 10%) Sn, tin bronzes often contain some phosphorus and sometimes lead or silver. These alloys provide the best combination of strength, electrical conductivity, and resistance to corrosion, as well as great versatility.

The probably most important family of the speciality alloys is that of the copper-aluminium alloys - the aluminium bronzes. Aluminium bronzes contain between 2 and 15% (w/w) Al, possibly with other alloying elements. When cold finished products are to be manufactured, the aluminium content is limited to 9% (w/w). Aluminium bronze alloys may also contain up to 4.5% Fe, 2 % Sn, 6%, Ni, 3.5% Mn and 3% Si to achieve special properties. These alloys combine good formability, good conductivity and high strength.

### 3.2.3 Solders

Alloys or pure metals are used as solders or brazing alloys. When their liquidus temperature is  $<450\text{ }^{\circ}\text{C}$  the process is called soft soldering, and when it is  $>450\text{ }^{\circ}\text{C}$  it is known as brazing. In high-temperature brazing, the operation is carried out in the absence of a fluxing agent and air, and the bonding metal has a liquidus temperature  $>900\text{ }^{\circ}\text{C}$ .

The main elements used in solders are copper, tin, zinc, silver, lead, cadmium and sometimes nickel, manganese or cobalt. An important class of brazing solders are the "General-purpose, cadmium-free brazing alloys". Their melting point is between  $700\text{ }^{\circ}\text{C}$  and  $1100\text{ }^{\circ}\text{C}$ .

Fluxes are organic or inorganic substances that remove oxides and other harmful layers from the surface to be joined by soldering or brazing. They thereby provide the conditions that allow wetting by the molten filler metal. Copper, copper - tin, or silver can be brazed in air without fluxes if phosphorus-containing copper-based brazing alloys are used. The phosphorus has a similar effect to that of a flux.

## 3.3 Molybdenite concentrate and Molybdenum trioxide

Molybdenite concentrate is the purified product of the flotation of molybdenite ore and consists of 90 – 95 % Molybdenum disulphide. Molybdenum disulphide is the raw material for molybdenum trioxide, which is the starting point of most applications of molybdenum. Some properties of Mo-compounds are listed in Tab. 3.1.

Molybdenum disulphide (CAS 1317-33-5;  $\text{MoS}_2$ ) is a black crystalline solid that occurs in two forms: hexagonal, which is found in the mineral molybdenite (CAS 1309-56-4) and rhombohedral. The solid is diamagnetic and a semiconductor. Lubricant-grade molybdenum disulphide consists of 99 %  $\text{MoS}_2$ .

Molybdenum trioxide (CAS 1313-27-5;  $\text{MoO}_3$ ) is the ultimate product of the oxidation of molybdenum compounds. It forms white orthorhombic crystals that are photosensitive, i.e., turn blue in light. The compound is weakly paramagnetic and an n-type semiconductor. It is produced by roasting mo-

lybdenum disulphide in air at 600 °C and may be purified by sublimation. It can also be prepared by reacting ammonium molybdate at 550 °C with oxygen or by precipitation from an aqueous ammonium molybdate solution treated with concentrated nitric acid (Sebenik et al. (1997)).

Tab. 3.1 Properties of molybdenum trioxide and dioxide and molybdenum disulphide (Sebenik et al. (1997))

| Property                                                                                   | MoO <sub>3</sub>      | MoO <sub>2</sub>                | MoS <sub>2</sub> |

## 4 Use / Application of Material

While copper keeps its chemical pure form until its end use as alloying element or final product in different applications, molybdenum is mainly won as molybdenite ( $\text{MoS}_2$ ) which is the purified concentrate that results from beneficiation. Molybdenite is the starting point for the production of technical-grade molybdenum trioxide and ferromolybdenum, which are used as alloying materials in the steel production.

### 4.1 Copper

Before end-use the pure metal produced in refineries or re-melting plants is manufactured into semi-fabricated products, such as shapes and ingots (known as “semis”). These manufacturing processes are subdivided into hot working, cold working and, if necessary, process annealing. These processes are dealt with in Part IXX - Metal Processing.

Few of the semis are ready for use as such. They more typically travel to first-stage manufacturers, who make metal rods, wire, and casting, and then to component manufacturers who produce such things as motors, valves, and insulated cables (Fig. 4.1). The components in turn are incorporated by final-stage manufacturers into a variety of finished products – automobiles, commercial buildings, residential housing, and so forth. These uses are shown in Tab. 4.1, they account for about 79% of the world-wide consumption of copper. The figures in Tab. 4.1 are useful guides to the relative use magnitudes, albeit these copper containing products are the basis for copper re-use. The relations between end-use, production and in- and export for Germany are given in Fig. 4.2.

Generally it can be said that copper is losing some traditional markets to other materials. One of them is for telecommunications cables, mainly due to increasing use of glass fibres and wireless devices for local distribution – the so-called “last mile”. Other traditional copper markets, such as copper roofing, copper water pipe, and brass hardware of all kinds are under pressure from cheaper materials, including aluminium, galvanised iron and plastics. On the other hand, copper is virtually irreplaceable for local distribution of electric power, household wiring, motor-generator windings, electronic circuitry and (as alloy) for some kinds of heat exchangers. Further substitution of copper by aluminium, in particular, seems unlikely.

**Fig. 4.1** Copper “semis” production. An illustration of the transformation of copper from pure metal fabrication flows through component manufacture (intermediate products) to a selection of final products. I and E indicate import and export flows, respectively (Graedel et al. (2002))

**Tab. 4.1** Principal end-uses of copper in 1990. RT is the average residence time of copper in the respective use; S/W is the estimated distribution between scrap (recovering) and waste (disposal/incineration) at the end of use (Graedel et al. (2002)).

| #  | Category               | Use (%) | RT (years) | S/W   |
|----|------------------------|---------|------------|-------|
| 1  | Building wire          | 14      | 45         | 50/50 |

## 4.2 Molybdenite concentrate

Flotation remains the preferred and almost exclusive method of upgrading the molybdenite mineral to an industrial-grade molybdenite concentrate containing 90 – 95 %  $\text{MoS}_2$  [1317-33-5], the balance being gangue.

Some commercial-grade molybdenite concentrate is subjected to additional grinding and flotation to produce lubricant-grade molybdenum disulfide (99 % MoS<sub>2</sub>). The purified product is added to grease and oils as a solid lubricant. Molybdenite is converted to technical-grade MoO<sub>3</sub>.

### 4.3 Molybdenum trioxide and Ferromolybdenum

Molybdenum is mainly used as an alloying element in steel, cast iron, and superalloys to increase hardenability, strength, toughness, and corrosion resistance. Initially, molybdenum was used in the lamp industry. Nowadays it is an increasingly important material in a wide range of applications (Tab. 4.2). In high-temperature applications, molybdenum competes with iron-, nickel- and cobalt-base superalloys, ceramics, and other high-melting metals (tungsten, tantalum, and niobium).

Molybdenite concentrate is converted to technical-grade MoO<sub>3</sub> by roasting it in air in a multiple-hearth furnace. The principal commercial molybdenum product is technical-grade molybdenum trioxide (MoO<sub>3</sub>) [1313-27-5]. In addition to being the major compound for adding molybdenum to steel, it is also the starting compound for all other molybdenum products including ammonium dimolybdate, pure molybdenum trioxide, sodium molybdate, molybdenum metal, and finally ferromolybdenum.

In the steel and foundry industry molybdenum is added to melts, either as technical oxide or in the form of ferromolybdenum [11121-95-2]. Compared to pure molybdenum, ferromolybdenum dissolves much more easily in the steel melt and is cheaper to produce.

The principal raw materials used for ferromolybdenum production are molybdenum concentrates and technical-grade molybdenum trioxide. Technical-grade molybdenum trioxide is commonly used as the molybdenum raw material. Two principal processes are used for molybdenum oxide reduction: carbothermic reduction in a submerged arc furnace and metallothermic reduction. The most commonly applied method is the silicothermic reduction, a type of metallothermic reduction (Sebenik et al. (1997)).

Tab. 4.2 Uses of molybdenum and molybdenum alloys (Sebenik et al. (1997)).

| Area of application                              | Examples of uses                                                                                                                                   |

## 5 System Characterisation

In this study the production of copper and molybdenum is modelled as coupled production system. In a first step the ore – jointly containing copper and molybdenum – is exploited. This mining and beneficiation step is formally a multi-output process, yielding copper concentrate and molybdenite concentrate. Depending on whether the raw material was an ore from primary molybdenum porphyry or from another sulphide deposit, either copper is the co-product or molybdenite. Since the coupled produced copper from primary molybdenum production is of no further importance, the coupled produced molybdenite from primary copper production accounts to 55% of the molybdenum production worldwide. The global molybdenite mix is thus formed together with the 40% “pure” molybdenite production, accounting for 95% of the overall molybdenum production (Fig. 5.1).

**Fig. 5.1** Schematic representation of the coupled production of copper and molybdenite in ecoinvent. RNA, RLA, RER, RAS, ID refer to the regions North America, South / Middle America, Europe, Russia / Asia, Indonesia / Australia; GLO is the global average.

The inventory representing the consumption of copper in Europe consists of a mix of imported primary metal from different parts of the world, imported copper concentrate which is refined in Europe itself, and secondary metal, which is partly recycled into foundries and partly into prior metallurgical steps (Fig. 5.2). As a proxy for Europe, the situation for Germany in 1994 is chosen.

The meta information on the modules described in this chapter are summarised in Tab. 5.1.

**Fig. 5.2** Schematic representation of the consumer mix of copper in RER in ecoinvent. As a proxy for Europe, the consumption pattern for Germany in 1994 is chosen.

**Tab. 5.1 Ecoinvent meta information for the processes for the production of primary copper and primary molybdenum.**

| Name                                  | mining copper ore                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             | copper, primary, at refinery                                                                                                                                                                                                                                    |

| General comment to reference function | The multi-output-process "mining copper-ore" delivers the co-products "copper concentrate, at beneficiation" and "molybdenum, molybdenite concentrate, couple production Cu". The product "copper concentrate" is intermediary required in the following copper production (5.2.5 Winning of primary copper in ecoinvent). The module "molybdenite concentrate" is designed for the use in Ecoinvent as starting material for the manufacturing of molybdenum trioxide and ferromolybdenum, both materials which used in the manufacturing of high quality steels and alloys. | The product "copper, primary, at refinery" is used as pure metal or as alloying element in various technical applications.                                                                                                                                      |
| CAS Number                            |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               | 7440-50-8                                                                                                                                                                                                                                                       |

| Geography text                        | This module is valid for the whole corresponding region. Some agents used like lime or sodium cyanide originate from data sets valid for Switzerland or Europe. Processes like blasting and transport originate from data sets valid for Switzerland or Europe.                                                                                                                                                                                                                                                                                                               | This module is valid for the whole corresponding region. Some agents used like lime or sodium cyanide originate from data sets valid for Switzerland or Europe.                                                                                                 |
| Technology text                       | Mining is done 70% open pit and 30% underground, followed by joint beneficiation of copper and molybdenite through flotation, where considerable amounts of agents are added. Overburden and tailings are disposed near the mining site.                                                                                                                                                                                                                                                                                                                                      | The ore is pre-treated, reduced and refined according to the country specific mix of process alternatives: reverberatory furnace 23.7%; flash smelting furnaces 60.7%; other 6.2%; SX-EW 9.4%. An overall abatement for sulphur dioxide of 45.4% was estimated. |
| Representativeness [%]                | 84                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            | 84                                                                                                                                                                                                                                                              |

| General comment to reference function | The product "blister copper", i.e. raw copper after converting with an average Cu content of 98%, is an intermediary product from primary copper production used uniquely in the secondary copper production. It makes 90% of the feed for secondary copper, whereas copper scrap makes the remaining 10%. | The product "copper, SX-EW, at refinery" is used in the production mix represented in module "copper, primary, at refinery" of the respective region.                                                                                                    |

| Geography text                        | This module is valid for the whole corresponding region. Some agents used like lime or sodium cyanide originate from data sets valid for Switzerland or Europe.                                                                                                                                            | This module is valid for an average world-wide process.                                                                                                                                                                                                  |
| Technology text                       | The ore is pre-treated and reduced according to the country specific mix of process alternatives: reverberatory furnace 6.2%; flash smelting furnaces 76%; other 17.8%. An overall abatement for sulphur dioxide of 95% was estimated.                                                                     | Heap leaching was assumed as average process. The ore is mined in open cut technique, leached and extracted with sulphuric acid and reduced by electro winning. For electricity mix a mix of 60% hydropower and 40% electricity at grid UCTE was chosen. |
| Representativeness [%]                | 94                                                                                                                                                                                                                                                                                                         | 100                                                                                                                                                                                                                                                      |

| General comment to reference function | The module describes the production of secondary copper in Germany with an output of 176'000 t copper cathodes in 1994. It is designed for the use of the metal as part of the supply mix "copper, at regional storage". It is not to be used if the impact of the secondary copper is considerable in a LCA study. In such cases, a more detailed assessment has to be conducted. | The product "copper, from imported concentrates, at refinery" is an auxiliary module used uniquely in the consumption mix in order to separate concentrate production and their transportation from different countries and the pyrolytical winning in RER. It does not contain any copper bearing inputs. |

| Geography text                        | This module is valid for one single very large plant, which is taken as proxy for production in RER.                                                                                                                                                                                                                                                                               | This module is valid for the whole corresponding region. Some agents used like lime or sodium cyanide originate from data sets valid for Switzerland or Europe.                                                                                                                                            |
| Technology text                       | In three different stages, different types of copper scrap and 10% of the feed of blister copper are refined to copper cathodes. Waste water is led to a communal treatment plant.                                                                                                                                                                                                 | The ore is pre-treated, reduced and refined according to the country specific mix of process alternatives: reverberatory furnace 6.2%; flash smelting furnaces 76%; other 17.8%. An overall abatement for sulphur dioxide of 95% was estimated.                                                            |
| Representativeness [%]                | 15.3                                                                                                                                                                                                                                                                                                                                                                               | 100                                                                                                                                                                                                                                                                                                        |

| General comment to reference function | The module describes the mining of molybdenite as main product. It is designed solely as part of the molybdenum production mix. The multi-output-process "mining of molybdenite" delivers the co-products "molybdenite concentrate, main product" and "copper, concentrate, couple production Mo". Molybdenite from coupled production module is designed for its use in the world-wide production-mix. | The module describes the production mix composed of molybdenite from coupled production in copper industry and molybdenite as main product. It is designed for the use in ecoinvent as starting material for the manufacturing of molybdenum trioxide and ferromolybdenum, both materials finally used in the manufacturing of high quality steels and alloys. |

| Included Processes                    | Transport of primary metal to Europe from the countries importing to Europe is included, as the import of concentrate, which is processed in RER. As import pattern the situation of Germany in 1994 was chosen.                            | The module includes the production of high grade primary molybdenum by pyro- and hydrometallurgical processes, the disposal of the slag, and the treatment of the waste water.                                                                                                                                                                                                                                                                                   |

| General comment to reference function | The module characterises the copper used in Germany in 1994, reflecting its origin and the fraction of secondary metal. It is designed for the use of the metal in various technical applications such as alloys and construction material. | Molybdenum is used e.g. in catalytic converters. It is not used for alloying steel, for which molybdenum trioxide or molybdenite are used. For lack of specific data, the metallurgical process of the zinc production is used as a proxy. Only the input of the concentrate is adapted. Although zinc and molybdenum concentrate are both sulfidic and the metal content is almost the same, this is a crude assumption and the data quality therefore is poor. |
| CAS Number                            |                                                                                                                                                                                                                                             |                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

## 5.1 Exploitation of copper ore

Copper ore is being mined for thousands of years. In the past decades the grades of worked copper ores continuously fell and dropped recently clearly below 1% world-wide (Fig. 2.1 for U.S. deposits). Nevertheless, mining and beneficiation techniques remain basically the same with open cut mining and flotation beneficiation. The hydrometallurgical process skips the beneficiation step in favour of a leaching step, which is followed by electro-winning.

### 5.1.1 Production process

**Mining.** Sulphidic copper ores are mined only 30% underground, the major part is mined in large open cut operations. According to (Ayres et al. (2002)) the ore mined in 1900 in the U.S. had a high content of 3.4% and was mined entirely underground. Open pit mining permits the use of very large equipment. Resulting economies of scale enable the exploitation of lower grade disseminated (porphyry) ores – the ores now mainly mined.

**Beneficiation.** After mining, the ore is first ground. In a next step it is subjected to gravity concentration to separate the metal-bearing particles from the unwanted minerals. After this first concentration step, flotation is carried out to remove the gangue from the sulphidic minerals. For neutralisation lime is added. In the flotation several organic chemicals are used as collector, frother, activator, depressor and flocculant. Sometimes cyanide is used as depressant for pyrite. Tailings usually are led to tailings heaps or ponds. As a result, copper concentrates containing around 30% Cu are produced. Molybdenite concentrate are further ground and purified. It leaves the process as co-product with a concentration of 90 – 95 % Molybdenum disulphide.

### 5.1.2 Emissions & Waste

#### Mining

The major emissions are due to mineral born pollutants in the effluents. Open cut mining generates large quantities of dust, which contains elevated contents of metals and sulphur. Rain percolates through overburden and accounts to metal emissions to groundwater. Overburden is deposited close to the mine.

#### Beneficiation

Ore handling and processing produce large amounts of dust, containing PM<sub>10</sub> and several metals from the ore itself. Flotation produces effluents containing several organic agents<sup>3</sup> used. Some of these chemicals evaporate and account for VOC emissions to air. Namely xanthates decompose hydrolytically to release carbon disulphide. Tailings effluent contains additional sulphuric acid from acid rock drainage.

Tailings are deposited as piles and in ponds. In the sulphidic tailings occurs acid rock drainage (ARD) over a long period of time. These effects are handled in the section “Non Ferrous Metal Winning – Auxiliary Processes”.

---

<sup>3</sup> Floating agents consist of collectors (xanthate or aerofloat) and frothing reagent (eg. Methyl Isobutyl Carbinol). Xanthanes are a broad class of organic salts formed by treatment of an alcohol with carbon disulfide in the presence of an alkali, potassium ethyl xanthate (KC<sub>3</sub>H<sub>5</sub>S<sub>2</sub>O, CAS No: 140-89-6). Aerofloat is a salt of carbonyldithiophosphoric acids. A widely used frothing reagent is e.g. methyl isobutyl carbinol, CAS: 108-11-2, syn. Methyl Amyl Alcohol.

### 5.1.3 Exploitation of copper-ore in ecoinvent

The modules describe the coupled production of copper- and molybdenum-concentrate in 1994 for different regions of the world and the world-wide production mix. Please note that in the database distinct datasets for the regions Northern America (RNA), South America (RLA), Europe (RER), Asia and Russia (RAS), Indonesia & Australia (ID) and the world-wide average (GLO) exist. However, in this report only the global (GLO) module is discussed in detail, the regional modules do not differ in their structure but only in their values. This module yields copper concentrate, which is used in pyrometallurgical processes. Hydrometallurgical copper winning – e. g. SX-EW – is based on different beneficiation techniques. Following modules in ecoinvent are covered in this chapter:

- mining copper ore (GLO)  
with the outputs:
  - copper, concentrate, at beneficiation (GLO)
  - molybdenum, molybdenite concentrate, coupleproduction Cu (GLO)
- mining copper ore (RNA)  
with the outputs:
  - copper, concentrate, at beneficiation (RNA)
  - molybdenum, molybdenite concentrate, coupleproduction Cu (RNA)
- mining copper ore (RLA)  
with the outputs:
  - copper, concentrate, at beneficiation (RLA)
  - molybdenum, molybdenite concentrate, coupleproduction Cu (RLA)
- mining copper ore (RER)  
with the outputs:
  - copper, concentrate, at beneficiation (RER)
  - molybdenum, molybdenite concentrate, coupleproduction Cu (RER)
- mining copper ore (RAS)  
with the outputs:
  - copper, concentrate, at beneficiation (RAS)
  - molybdenum, molybdenite concentrate, coupleproduction Cu (RAS)
- mining copper ore (ID)  
with the outputs:
  - copper, concentrate, at beneficiation (ID)
  - molybdenum, molybdenite concentrate, coupleproduction Cu (ID)
- copper, concentrate, at beneficiation (RNA)
- copper, concentrate, at beneficiation (RLA)
- copper, concentrate, at beneficiation (RER)
- copper, concentrate, at beneficiation (RAS)
- copper, concentrate, at beneficiation (ID)

The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.3 and Fig. 5.4. Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 17. The following paragraphs describe calculations, sources and assumptions chosen in this study.

## Allocation

The ecological burden of the copper ore mining is distributed among the coupled products copper concentrate and molybdenite concentrate. As allocation procedure the revenue is chosen. The molybdenum price is quoted as US\$ per kilogram molybdenum content in molybdenite concentrate. This price is stable since 1983 with a value of around US\$ 5.75 per kg Mo (USGS (2003)), this gives a revenue of US\$ 3190 per tonne molybdenite concentrate with an assumed composition of 92.5% MoS<sub>2</sub>. Copper concentrate is traded in large quantities. The price of copper concentrate could not yet be assessed; it is estimated with the final bids of three auctions held in 2000 on an online web-auction<sup>4</sup> resulting in an average price of 15.3 US cents per pound copper payable for refining and smelting. With a copper price of 0.95 US\$/kg a price of 522 US\$ per tonne of concentrate with 29.7% copper content is calculated. These assumptions lead to an average revenue of 17 US\$ and 1816 US\$ per tonne molybdenite and copper, respectively, contained in the ore – with the metallurgical yield included – and thus to an allocation factor of 1% and 99% for molybdenite and copper concentrate, respectively.

## Infrastructure and land use

The production infrastructure used directly for exploitation is inventoried within this module, whereas the infrastructure like buildings and land-use for the operation is inventoried within auxiliary modules, which comprises both mining and beneficiation facilities. These datasets are treated in the part auxiliary processes of this report. The mobile equipment used for exploration like drilling machines, scoop trams and underground trucks is inventoried with the diesel consumption of 69.2 kJ per tonne mined raw ore. The used module “diesel, burned in building machine” includes the infrastructure of the machines. Conveyor belts are further assumed with a capacity of 2000 t/h which yields 7.6E-5 m conveyor belt required per tonne mined raw ore (Tab. 5.2).

According to Part XX, Non Ferrous Metal Winning – Auxiliary Processes, land use was assessed with the value for open pit mining (0.0025 m<sup>2</sup>/t) and the respective share in the world copper (70 %) production, yielding a 0.00174 m<sup>2</sup>/t and 0.0522 m<sup>2</sup>/t respectively. For underground mining no direct land use is estimated. A lifetime of 30 years is assumed.

**Tab. 5.2 Assumptions for the infrastructure used in underground mining exploitation. As lifetime ten years are estimated, and 5000 working hours yearly.**

| action      | share | machine        | throughput   | unit       | infrastructure  |
|-------------|-------|----------------|--------------|------------|-----------------|
|             |       |                | t / lifetime | Length (m) | m / t ore mined |
| Open pit    | 70%   | Conveyor belts | 100'000'000  | 2000       | 1E-5            |
| Underground | 30%   | Conveyor belts | 100'000'000  | 2000       | 2E-5            |
| Mix         |       |                |              |            | 7.6E-5          |

## Mining

In the considered process the ore is mined mainly in open cut operations. According to Martens et al. (2002) 69.6 % of the copper world production originates from open pit mines, but no further differentiation in regions or countries was available. Hence the world average is used for all regions. The overburden is disposed in piles near the mine, the standard module for disposal of non-sulphidic over-

<sup>4</sup> <http://www.copperconcentrate.com/default.asp>, accessed on 01.03.2003

burden was chosen, which includes the land use and transformation through the disposal. No overburden is refilled according to Krauss et al. (1999), the amount is documented for each of the five world regions. Also water use is documented, but as overall value, which is comprised in the following beneficiation step. Concerning electricity supply mix, Hilbrans & Hinrichs (1999) assume for the nickel-production a share of 60% of hydropower due to the operations high and constant energy demand. This assumption is used also in this inventory.

### **Beneficiation**

Once the ore is mined, it is ground and conditioned for further concentration. Considerable amounts of lime and flotation agents are added. The separated gangue is disposed in tailings ponds; the concentrated ore is fed to the metallurgy, which is assumed to be on-site. The respective standard module “disposal, sulphidic tailings, off-site” is chosen. (see “Non Ferrous Metal Winning – Auxiliary Processes”, Chapter “Disposal of Tailings and Overburden”).

The infrastructure of beneficiation is included in the mining infrastructure. Dust emissions comprise additionally the dust emissions due to mining activities. Like in the mining step, a share of 60% hydroelectricity was chosen according to Hilbrans & Hinrichs (1999).

**Lime:** Lime input was documented in Krauss et al. (1999) for each process alternative with a range of 1200–1330 g / t ore.

**Steel:** The steel input for milling (substitution of components for abrasion) was documented and ranges from 690 to 920 g/t with an average of 765 g/t ground ore assumed herewith. The mill work consists of special austenitic manganese steel of Hadfield grade, which is inventoried with chromium steel as a proxy.

**Reagents:** No exact information on mass and nature of the floating agents used had been available, therefore general values were assessed in Krauss et al. (1999) based on values in year 1978. Newer values reported in IPPC (2001) have been taken in this study (Tab. 5.4). For copper mining a range of 25 – 300 g collector and 25 – 250 g frothing reagent per tonne sulphidic ore was recommended in (Krauss et al. (1999)). This is confirmed by the values in Tab. 5.4. Collector and frother are inventoried for ecoinvent as unspecified organic chemicals. According to NPI (2001), xanthates hydrolytically decompose to 0.53 mg carbon disulphide per mg xanthate. With 189 g xanthates per tonne ore from Tab. 5.4 this corresponds to 100 g carbon disulphide per t mined ore (Tab. 5.5).

Activator and Depressants – excluding sodium cyanate – are modelled as unspecific inorganic chemicals; their emission to water is covered by the emissions reported from mining sites, which are shown in Tab. 5.3.

For pH adjustment and leaching, the value for sulphuric acid was considered with 3.74 kg/t ore mined (Tab. 5.5). As sulphuric acid is a by-product from the metallurgy, its production is regarded as burden free. Requirement of other acids is neglected. Acid emissions to water due to the use of sulphuric acid are not accounted.

Since composition and environmental fate of activator, depressant and sulphuric acid is uncertain, reported data for total emissions shown in Tab. 5.4 are taken. Note, that some theoretical emissions due to the use of the reagents are higher than the reported ones in Tab. 5.3.

Sodium cyanide is widely used for extracting gold and other metals such as silver, copper, and zinc. It is used as leachate and as depressant for certain sulphidic minerals. A cyanide recovery of 80 – 90% is reported due to abatement and recovery in the Golden Cross mine in New Zealand (Anonymous (1998a)). Here a value of 80% is chosen for cyanide-abatement technology. With a reported use of 35 g NaCN per tonne ore mined (Tab. 5.4), this means a direct emission of 3.88 g HCN per tonne ore mined. An overview of the reagents accounted for is presented in Tab. 5.5.

**Water use & Effluents:** Water use was documented in Krauss et al. (1999) and has been inventoried in this study as originating from river without pumping activities. Additional to direct emissions due to

the use of chemicals, total emissions to water are chosen according to Tab. 5.3. These values are from base metal sites, and are thus only an approximation for the real effluent concentrations in the copper production. It is assumed here that the effluents also include acid rock drainage (ARD). ARD after mine closure is modelled in the module “disposal, sulphidic tailings, off-site”. Effluent volume was not documented in Krauss et al. (1999); for this study it has been assumed that the water requirements equal the effluents.

**Dust:** A case study in Anonymous (1998b) on a projected open cut gold-copper mining and processing facility in Australia predicts for dust emissions per tonne of ore mined values between 0.18 kg/t and 0.46 kg/t. The prediction was made using the Emission Estimation Technique Manual for Mining (NPI (2001)). The maximum value of 0.46 kg/t is chosen for total dust emissions. According to the IAEA<sup>5</sup> the dust composition is approximated with values of a specific sulphidic nickel ore in Tab. 5.6. For PM<sub>10</sub> values, the ratio TDS : PM<sub>10</sub> : PM<sub>2.5</sub> was approximated with values from copper ore mining 101.72 : 50 : 5 g / t ore taken from the CEMIP-database<sup>6</sup>, i.e. one tonne emitted dust corresponds to 491.5 kg PM<sub>10</sub> and 49.2 kg PM<sub>2.5</sub> respectively. The airborne emissions resulting from mining and beneficiation activities are summed up in Tab. 5.6. In ecoinvent, for particulates differential classes are used adding up to the total dust emission, i. e. 49.2 kg PM<2.5, 442 kg PM2.5-10 and 508 kg PM>10.

### Data quality

**Mining;** Data for major mass fluxes are satisfactory, while the emissions into water may be overestimated due to different system boundaries of reported effluent volume from (Krauss et al. (1999)) and total effluent emissions reported in (IPPC (2002)). High uncertainties are reflected by a high standard deviation (stdev95) of 10.

**Beneficiation;** Like in mining, the emissions to water can be overestimated. The emissions from tailings are assessed in an external module, which itself contains rough assumptions of a global overburden and tailings composition and a simplified disposal scenario. Emissions though can vary considerably from case to case.

**Tab. 5.3** Composition of effluents from mining activities; values are taken from total emissions to water from base metal sites in (IPPC (2002)).

| Compound        | Unit                    | Range         | This study<br>(geometric mean) | Number of<br>Samples |
|-----------------|-------------------------|---------------|--------------------------------|----------------------|
| Discharge       | Mio. m <sup>3</sup> / a | 0.08 - 22.9   | 3.65                           | 6                    |
| Ca              | g / m <sup>3</sup>      | 686           | 686                            | 1                    |
| SO <sub>4</sub> | g / m <sup>3</sup>      | 1750 - 3175   | 2357                           | 2                    |
| COD             | g / m <sup>3</sup>      | 2.24 - 48.5   | 10.4                           | 2                    |
| Solids          | g / m <sup>3</sup>      | 2.38 - 11.3   | 5.17                           | 4                    |
| Al              | mg / m <sup>3</sup>     | 69.3 - 108    | 86.3                           | 2                    |
| As              | mg / m <sup>3</sup>     | 0.264 - 14.1  | 2.95                           | 3                    |
| Cd              | mg / m <sup>3</sup>     | 0.0901 - 1.02 | 0.316                          | 4                    |
| Co              | mg / m <sup>3</sup>     | 0.742 - 0.823 | 0.781                          | 2                    |
| Cr              | mg / m <sup>3</sup>     | 0.0311 - 9.62 | 0.547                          | 2                    |
| Cu              | mg / m <sup>3</sup>     | 1.24 - 44.9   | 7.91                           | 5                    |
| Fe              | mg / m <sup>3</sup>     | 61.7 - 1326   | 291                            | 3                    |
| Mn              | mg / m <sup>3</sup>     | 24.7          | 24.7                           | 1                    |
| Hg              | mg / m <sup>3</sup>     | 0.0155 - 0.12 | 0.0377                         | 3                    |
| Ni              | mg / m <sup>3</sup>     | 0.792 - 1338  | 24.3                           | 3                    |
| Pb              | mg / m <sup>3</sup>     | 0.0155 - 20   | 2.80                           | 4                    |
| Zn              | mg / m <sup>3</sup>     | 5.37 - 225    | 75.9                           | 5                    |
| N               | g / m <sup>3</sup>      | 2.50 - 1786   | 22.8                           | 3                    |

**Tab. 5.4** Consumption of reagents in base metal mineral processing plants. Data taken from (IPPC (2002)).

| Reagents                                                                                 | Unit | Range       | This study<br>(geometric mean) | Number of<br>samples |
|------------------------------------------------------------------------------------------|------|-------------|--------------------------------|----------------------|
| Collectors – Xanthate                                                                    | g/t  | 110 - 300   | 188.6                          | 6                    |
| Frothers - Sylvamine, MIBC, Dowfroth                                                     | g/t  | 9.7 - 150   | 37.2                           | 5                    |
| Sodium cyanide                                                                           | g/t  | 4 - 310     | 35                             | 2                    |
| Depressants – Zinc sulphate, Iron sulphate, Acetic acid, Sodiumchromate, Dithiophosphate | g/t  | 35 - 432    | 231.5                          | 5                    |
| Activator - Copper sulphate                                                              | g/t  | 433 - 876   | 538                            | 4                    |
| Flotation agents                                                                         | g/t  | 19.0        | 19.0                           | 1                    |
| Flocculants - CMC                                                                        | g/t  | 1 - 100     | 11.1                           | 3                    |
| Sulphuric acid (pH)                                                                      | g/t  | 387 - 12000 | 3739                           | 4                    |
| Sodium hydroxide (pH)                                                                    | g/t  | 30 - 490    | 121                            | 2                    |
| Nitric acid (pH)                                                                         | g/t  | 150         | 150                            | 1                    |
| Hydrochloric acid (pH)                                                                   | g/t  | 1           | 1                              | 1                    |

**Tab. 5.5 Emissions and input due to chemical use in beneficiation in g per tonne treated ore. The values are the ones chosen in this study. For further details read in text.**

| Reagent              | Type of burden     | Unit | Chosen value                      |
|----------------------|--------------------|------|-----------------------------------|
| Collector            | input technosphere | g/t  | 189                               |
| Carbon disulfide     | air emission       | g/t  | 100                               |
| Frother              | input technosphere | g/t  | 37                                |
| Lime                 | input technosphere | g/t  | 2000                              |
| Carbon dioxide       | air emission       | g/t  | inventoried in metallurgical step |
| Activator/Depressant | input technosphere | g/t  | 828                               |
| Sulphuric acid       | input technosphere | g/t  | 3739                              |
| Sodium Cyanide       | input technosphere | g/t  | 35.2                              |
| Cyanide              | water emission     | g/t  | 3.88                              |

**Tab. 5.6 Emissions to air resulting from mining and beneficiation. Values for total dust emission are taken from NPI 2001**

| Emission to air |    | Unit         | Emission per tonne mined ore |
|-----------------|----|--------------|------------------------------|
| Antimony        | Sb | mg / mg dust | 0.0000002                    |
| Arsenic         | As | mg / mg dust | 0.0000015                    |
| Beryllium       | Be | mg / mg dust | 0.0000026                    |
| Boron           | Be | mg / mg dust | 0.00001                      |
| Cadmium         | Cd | mg / mg dust | 0.00000011                   |
| Chromium        | Cr | mg / mg dust | 0.0001                       |
| Cobalt          | Co | mg / mg dust | 0.00002                      |
| Copper          | Cu | mg / mg dust | 0.00005                      |

Fig. 5.4 Flows for “Mining of copper-ore, GLO – part mining” and its representation in the ecoinvent database. Values correspond to the functional unit of 1 kg copper ore.

## 5.2 Winning primary copper

The standard process for the pyrometallurgical production of primary copper in use since the late 19th century involves three major stages:

1. ore mining and beneficiation,
2. smelting and desulphurisation and
3. final refining.

The newer hydrometallurgical process, known as solvent extraction-electro-winning (SX-EW), is in a rapid growth stage and it is to some extent displacing the older pyrometallurgical approach. The pyrometallurgical approach is a net producer of by-product sulphuric acid, whereas the hydrometallurgical process is a net consumer of the acid. Thus, in the long run it is likely that the two will be increasingly combined.

In this study primary copper production is modelled as an aggregation of the pyrometallurgical and SX-EW production routes using the region-specific shares along with (Krauss et al. (1999)).

**Tab. 5.7 Overview of the shares of different production processes in different regions, in million tonnes, and the share of SX-EW (Krauss et al. (1999)). Note that the two regions North America and South America are not distinguished and therefore concerning sulphur dioxide emissions are treated as one in this study.**

### 5.2.1 Production process and infrastructure

There are many different process possibilities to win the metal. The chosen process depends on the composition of the ore, the local costs of energy supply, and the local legislation. Basically two differ-

<sup>7</sup> Commonwealth of Independent States

ent types can be distinguished: the hydrometallurgical and the pyrometallurgical process with a share of 90.6 % and 9.4 % of the world-wide copper produced in 2004. The hydrometallurgical process is described in detail later in Section 5.3 Hydrolytic winning of primary copper.

**Pyrometallurgy;** The pyrometallurgical treatment of copper concentrates includes three types of unit operation: drying & roasting (pre-treatment), smelting & converting (reduction), and finally refining. In the roasting step sulphur is driven off as sulphur dioxide and part of the iron is oxidised. In smelting, the roaster product is melted with a siliceous flux which combines with the oxidised iron to produce two immiscible phases, a liquid silicate slag which can be discarded, and a solution of molten sulphides which contains the metal values. In the converting operation on the sulphide melt, more sulphur is driven off as sulphur dioxide, and the remaining iron is oxidised and fluxed for removal as silicate slag, leaving a high-grade copper sulphide matte. In several modern operations the roasting step has been eliminated, and the copper sulphide concentrate is treated directly in the smelter. The converted copper is referred to as blister copper with a purity of 98%.

**Refining;** Conventional refining comprises three stages: (1) pyrometallurgical or fire refining, (2) electrolytic refining, and (3) remelting of cathodes and casting of shapes. Fire refining is applied to crude copper from converters and furnaces, cement copper from hydrometallurgy, anode scrap from electrolytic refining, and high-grade copper scrap, chiefly unalloyed wire scrap. About 80 % of the world copper production is refined by electrolysis. This treatment yields copper with high electrical conductivity and provides for separation of valuable impurities, especially precious metals. Copper cathodes must be remelted and cast to shapes because the structure of copper formed by electrocrystallization is not suitable for working to semi finished products. Cathodes are remelted in several types of special furnaces that perform the tasks of melting, post refining (if necessary), holding, and casting.

## 5.2.2 Emission

### Metallurgy

**Sulphur dioxide;** In every process steps sulphur dioxide is emitted to air. Recovery of sulphur dioxide is only economic for high concentrated off-gas. SO<sub>2</sub> emissions are by far the most important in the metallurgy.

**Carbon dioxide;** In the beneficiation step, considerable amounts of lime is added to the ore for pH-stabilisation. Lime forms later flux in the metallurgical step. Lime decomposes into CO<sub>2</sub> to form calcite.

**Dust;** Dust carries over from the roasting, smelting and converting processes. Particulate emissions to air consist of metals and thus are often returned to the leaching process after treatment.

**Emissions to water;** Metals and their compounds and substances in suspension are the main pollutants emitted to water. The metals concerned are Cu, Ni, Co, As, and Cr. Other significant substances are chlorides and sulphates. Wastewater from wet gas cleaning (if used) of the different metallurgical stages is the most important source. The leaching stages are usually operated on a closed circuit and drainage systems, and are therefore regarded as minor sources.

### Refining

Also in this step the combustion of sulphur leads to emissions of SO<sub>2</sub>. Nitrogen oxides are produced in significant amounts during acid digestion using nitric acid. Chlorine and HCl can be formed during a number of digestion, electrolytic, and purification processes. Dust and metals are generally emitted from incinerators and furnaces. Organic compounds, namely dioxins, can be emitted from smelting stages resulting from the poor combustion of oil and plastic in the feed material. All these emissions are subject to abatement technologies and controlling. Large quantities of effluents contain substantial amounts of metals and organic substances.

### 5.2.3 Waste

#### Metallurgy & Separation from Non Ferrous Metals

The production of metals is related to the generation of several co-products, residues and wastes, which are listed in the European Waste Catalogue. Some of the process specific residues can be reused or recovered in preliminary process steps (e. g. dross, filter dust) or construction (e. g. cleaned slag). Residues also arise from the treatment of liquid effluents, the main residue being gypsum waste and metal hydroxides from the wastewater neutralisation plant. These residuals have to be disposed, usually in lined ponds.

#### Refining

Like in the pyrometallurgical step, considerable quantities of solid residuals are generated, which are mostly recycled within the process or sent to other specialists to recover any precious metals. Final residues generally comprise hydroxide filter cakes (iron hydroxide, 60% water, cat I industrial waste).

### 5.2.4 Copper, blister copper, at primary smelter in ecoinvent

This module is uniquely used in the secondary copper production where, besides copper scrap, 10% of the feed consists of blister copper, i.e. raw copper after converting with an average content of 98%. The inventory of this module is identical to that of the primary production of copper in RER, with the only difference that the refining step is omitted and with 98% of the in- and outputs, since the metal content of blister copper is only 98%. The inventory has an output of 1 kg blister copper.

### 5.2.5 Winning of primary copper in ecoinvent

This part is mainly based on Krauss et al. (1999). The general process description was taken from Fabian (1997), whereas the process specific emissions are from IPPC (2001) and EEA (1999). In Krauss et al. (1999) data for the different process alternatives in copper production was collected in detail. The distinction there was made between procedures depending on different furnaces: Inco, Teniente, Outokumpu, Mitsubishi, Noranda, Vanyukov, reverberatory furnace, electric furnace, Kivcet. According to the share of the different procedures in the respective countries an aggregated production mix for a country was calculated (Tab. 5.7). Where applicable, the respective share in SX-EW – copper is included into the production mix.

Please note that in the database distinct datasets for the regions Northern America (RNA), South America (RLA), Europe (RER), Asia and Russia (RAS), Indonesia / Australia (ID), and the world-wide average (GLO) exist. However, in this report only the global (GLO) module is discussed, the regional modules do not differ in their structure but in their values according to Tab. 5.8.

The module describes the production mix for refined copper in 1994. It is designed for the use of the metal as raw material for the semis manufacturing or as alloying element. The modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.5, Fig. 5.6 and Fig. 5.7. The meta information for this process in ecoinvent are summarised in Tab. 5.1 on page 17 ff. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one kilogram of cathode copper.

#### Metallurgy

In this study all nine process alternatives from Tab. 5.7 have been considered according to their production share given in Krauss et al. (1999). These alternatives cover 84 % of the world production of primary copper. The inventory already is partly aggregated and reflects the mix of the different process alternatives within a certain process step, e.g. electricity consumption in the roasting step. For de-

tails on single process alternatives, e. g. the Outokumpu – process, please consult Krauss et al. (1999) or IPPC (2001).

**Pre-treatment;** Flux demand (quartz sand) is documented in Krauss et al. (1999). Additional 250 kg of limestone per tonne of copper has been assumed in this study according to Ayres et al. (2002). Drying is done by gas. Of the electricity 40% is assumed to originate from the grid while run-off plants deliver 60%. Sulphuric acid produced from off-gas is not inventoried (cut-off). All process specific emissions are inventoried in the smelting step.

**Smelting and Reduction;** 40% electricity is from grid, 60% hydropower assumed. A production of steam is reported which is not inventoried as by-product. Dross and slag are reported to be recycled, for this study however they are assumed to be disposed of in a landfill. In this step the major part of the sulphur dioxide is emitted, which represent the main impact besides the energy use. The values for emissions vary in a wide range from 4 kg to 2000 kg SO<sub>2</sub> per tonne metal produced (Anonymous (1998c)), but single values of much higher magnitude are also reported, e. g. nickel-copper smelting in Noril'sk (RUS) with 5300 kg SO<sub>2</sub> / t metal produced (Hochfeld (1997)). The target for “best available technique” in Europe is set to 6 – 16 kg SO<sub>2</sub> / t Cu (IPPC (2001)), the World Bank mentions 25 kg SO<sub>2</sub> / t Cu for “modern plants using good industrial practices”. SO<sub>2</sub> emissions depend basically on the possibility of economical recovering. Recovering of sulphur dioxide as sulphuric acid is economic if the SO<sub>2</sub> content in the off-gas is sufficient and therefore is dependent from the production process and the control-factor (abatement). In this study following emission factors are chosen relating to Tab. 5.7: reverbatroy furnace and undefined processes (“other”): 2500 kg / t Cu; all other alternatives: 150 kg / t Cu. The control-factors chosen are shown in Tab. 5.7, they are based on Ayres et al. (2002). For this calculation the regions North and South America are treated equally due to missing specific data. The resulting SO<sub>2</sub> emissions are shown in Tab. 5.8; they range from 36 kg / t Cu (RER) to 1296 kg / t Cu (ID) with a world average of 458 kg / t Cu. The calcination of previously added lime (pre-treatment and beneficiation, see Section 5.1.3 Exploitation of copper-ore in ecoinvent) releases 0.44 kg CO<sub>2</sub> per tonne lime. Several emissions to air are documented for European conditions in EEA (1999); the resulting emissions are chosen for this study (Tab. 5.9). Elaborate abatement technology – values of column “impact control” in Tab. 5.8 – are applied only for RNA and RER, whereas for the other regions values corresponding to limited control are chosen. VOC emissions are mentioned in EEA (1999) with a value of about 0.015 kg / t (unabated, including roasting and smelting). Dust emissions according to Anonymous (1998c) range between 0.1 kg / t Cu and 20 kg / t Cu, whereas IPPC (2001) mentions for modern European plants a range of 0.16 kg / t Cu to 1 kg / t Cu. In this study 0.4 kg / t Cu is chosen, which is assumed to apply for all covered processes. The distribution of particulate sizes is taken from CEPMEIP<sup>8</sup> (Tab. 5.10). For water use the value for primary nickel production of 1.4 m<sup>3</sup> per tonne concentrate worked is chosen (Hochfeld (1997)). The volume of the effluent is assessed with the value for water use and respective emissions into water are calculated according to the content in Tab. 5.11.

**Refining;** No further wastes are considered from this step. Region's specific production mix is compiled with the specific pyrolytical technologies and the specific share in SX-EW – copper.

| 1) Krauss et al. (1999) give different values for copper content in concentrates and for concentrate consumption (per t of copper) in the chapters for mining and for metallurgy. For consistency within the data, the values given in the mining chapter are used in ecoinvent. |                 |      |       |       |      |      |      |      |

**Tab. 5.9 Metal emission factors to air for primary copper production (EEA (1999)).** Chosen value is the average of the given range. Missing ranges – tagged with \* – have been extrapolated from limited / impact control with the average factor of 20. Values for “impact control” apply only to RNA and RER.

### Data quality

Process data is satisfactory and valid for over 84 % of the primary copper production. The main emissions dominating possibly the whole process is sulphur dioxide, which itself is not reported in Krauss et al. (1999). Reported values range in two orders of magnitude. Poor data is available on composition and fate of solid waste, for which the reuse rate was not documented. High uncertainties in volume and composition of the effluents are assumed.

Fig. 5.7 Flows for “copper, primary, at refinery, GLO – part refining” and its representation in the ecoinvent database. Values correspond to the functional unit of 1 kg copper.

## 5.3 Hydrolytic winning of primary copper

This part is mainly based on (Krauss et al. (1999)). The general process description was taken from (Fabian (1997)). Process specific emissions derived from (IPPC (2002)) and (IPPC (2001))

### 5.3.1 Production process and infrastructure

Oxide ores and supergene sulphide ores (i.e. ores not containing iron) can be recovered most easily by hydro-metallurgical techniques. The general steps of mining and refining are identical to those described in Section 5.1 Exploitation of copper ore. The difference in this type of production is in the beneficiation and the metallurgical step. Hydrometallurgical process is only applicable to oxidic ore, sulphides have to be roasted prior to leaching.

Several hydrometallurgical processes are in commercial operation for the treatment of copper mattes to copper cathodes. The dominant process in the copper production is the solvent extraction-electrowinning (SX-EW), which essentially by-passes the beneficiation and smelting stages, substituting a leaching stage followed by cementation or electro-winning.

Hydrometallurgical processes can generally be subdivided into the following steps (Fabian (1997)):

1. Pre-treatment, physical (e.g., comminution, grinding) or chemical (e.g., roasting)
  2. Leaching, chiefly with sulphuric acid or ammoniacal solutions, sometimes under oxidising conditions. In copper production, leaching is used in a number of ways:
    - In situ leaching, applied in loose ore bodies. In situ leaching recovers copper from small oxide ore bodies (too small to mine economically) or worked-out underground mines. Dump leaching is used to recover copper from large quantities (millions of tonnes) of strip mine waste with a very low grade. Dilute sulphuric acid is trickled through the material. Once the process starts it continues naturally if water and air are circulated through the heap. The time required is typically measured in years. Sulphur dioxide is emitted during such operations. Soluble copper is then recovered from drainage tunnels and ponds. Copper recovery rates vary from 30% to 70%.
    - Dump or heap leaching of lumpy or ground material. Heap leaching is essentially the same as dump leaching, except that it is applied to oxide ores, which are previously ground or crushed and heaped on a prepared surface.
    - Vat or percolation leaching of small-sized material. In vat leaching, oxide ores are crushed and placed in large concrete vats (up to 18,000 tonnes capacity), then flooded by concentrated sulphuric acid, which converts most of the copper to copper sulphate. Extraction of one tonne of copper from ore with a grade of 1% requires 4400 litres of 96% sulphuric acid. Vat leaching typically recovers 75% of the copper. The process is fairly rapid (hours to days).
    - Agitation or slime leaching of fine-grade material without pressure
    - Pressure leaching of fine-grade material with or without oxygen
- In practice, only a few proven chemicals, lixivants, are used: Dilute sulphuric acid for basic carbonates and sulphates, and silicates; Solutions of iron (III) salts (sulphate) as oxidising agents in sulphuric acid for sulphidic ore; Ammoniacal solutions of ammonium salts (carbonate) for oxidised ores. Recently, the bacteria-assisted leaching of low-grade copper ores and industrial wastes has been developed. Certain autotrophic bacteria accelerate the oxidation of copper and iron sulphides. Typical species are *Thiobacillus thiooxidans*, the reaction takes place slowly in atmospheric oxygen (Acid Rock Drainage), but the bacteria catalyse it.

3. Solution cleaning, e.g. by precipitation of impurities and filtration or selective enrichment of copper by solvent extraction or ion exchange. The solvent extraction process comprises two steps: selective extraction of copper from an aqueous leach solution into an organic phase (extraction circuit) and the re-extraction or stripping of the copper into dilute sulphuric acid to give a solution suitable for electro winning (stripping circuit).
4. Separation, precipitation of copper metal or copper compounds such as  $\text{Cu}_2\text{O}$ ,  $\text{CuS}$ ,  $\text{CuCl}$ ,  $\text{CuI}$ ,  $\text{CuCN}$ , or  $\text{CuSO}_4 \cdot 5 \text{H}_2\text{O}$  (crystallisation)
5. Post-treatment, e.g., fire-refining of crude cement copper or thermal reduction of copper compounds

However, because solvent extraction-electro-winning (SX-EW) requires ten times as much electrical energy as classical electrolytic refining ( $2000 - 2600 \text{ kWh t}^{-1}$ ), and because established solvent extraction techniques do not work well on copper sulphide ores, electro-winning techniques have remained complementary to smelting. Today about 10 – 15% of the world copper production is from SX-EW of copper oxide ores (Graedel et al. (2002) and Krauss et al. (1999)).

### 5.3.2 Emissions and wastes

Several emissions to air and water occur in the mining step. These emissions are identical to those in the conventional mining process and are shortly discussed there.

**Pre-treatment;** In the eventual roasting step to remove sulphides, considerable amounts of sulphur dioxide may be emitted into the air, since the concentration of sulphur dioxide in the off-gas probably is too small for recovery as sulphidic acid. Contrary to the beneficiation step of the pyrometallurgical process, no tailings develop additionally to the mining.

**Leaching;** For in-situ and heap leaching considerable amounts of sulphuric acid and leaching agents emit into water and air. No figures are currently available on the dimension of such emissions. After the solvent-solvent extraction, considerable amounts of leaching residues remain, which consist of undissolved minerals and the remainders of leaching chemicals.

**Electro-winning;** Most of the electrolyte and the sulphuric acid is recovered into the leaching step. Presumably no considerable wastes and emissions occur, but there are no available data.

### 5.3.3 Hydrolytic winning of primary copper in ecoinvent.

This part is mainly based on (Krauss et al. (1999)). The general process description was taken from (Fabian (1997)), but no process specific emissions were documented there.

The module describes the production of copper with the SX-EW process. It is designed for the use of the metal as part of the production mix “copper, primary, at plant”.

The modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.8 and Fig. 5.9. Ecoinvent meta information for this process is summarised in Tab. 5.1 on page 17 ff. The following paragraphs describe calculations, sources and assumptions made in this study. The functional unit of this process is one kilogram of cathode copper.

**Mining;** Mining is similar to what is described in Section 5.1 Exploitation of copper-ore, but no beneficiation occurs. No exact information on the mining step is available in Krauss et al. (1999), therefore a mining process described in the previous section has been chosen as proxy. This is done with specific values for diesel use, explosives, and energy according to open pit mining. For further details please consult the Section mentioned above. Data on ore input, overburden, and gangue are documented in Krauss et al. (1999). Since no further information is available on presumably used crushing

and grinding operations of the material, they have been estimated with additional energy and mechanical wear (milling equipment) from the conventional copper-beneficiation in RLA. No use of conditioning agents is to be expected.

**Pre-treatment: Leaching and extraction;** Following Krauss et al. (1999), heap leaching is considered as leaching process. Of the total electricity use of 600 kW /t Cu, 250 kWh/t Cu and 350 kWh/t Cu are required for leaching (sprinkling) and extracting (pumping), respectively. Krauss et al. (1999) state a loss of 171 m<sup>3</sup> / t Cu leachate through infiltration and evaporation, and 1.7 t / t Cu sulphuric acid and 276 t / t Cu leaching residues but their fate is not evident. Since no information on the magnitude of leachate loss into the ground exists, no emissions to water are considered. Thus additional emissions of heavy metals, and sulphate into the ground are to be expected. Leaching agents were inventoried with the inventory of ammonia production as proxy.

**Electro-winning and Refining;** Use of sulphuric acid was in no case inventoried, since it is treated in this study as by-product of pyrolytical winning of metals from sulphidic ores. No further emissions or wastes are considered important, since the electrolyte is fully recycled to the leaching stage. Losses in electrolyte and leachate are inventoried in the pre-treatment step.

### **Data quality**

There is not sufficient information for declaring this data set of good data quality. In particular, uncertainty for energy consumption in a likely additional crushing / milling step (not modelled herewith) and probable leaching to ground may lead to an underestimation of the environmental impacts. Since the energy consumption considered for electro-winning is much higher than in the pyrolytical processes, this will probably dominate the environmental impacts; thus, the disregard of beneficiation and leaching impacts may be compensated.

## 5. System Characterisation

| General Flow Information                    |                                                      |        | Representation in ecoinvent                                                           |                                                                      |                        |                            |          |                                                                           |                                                       | Uncertainty Informations |                       |      |                    |                  |                 |

## 5.4 Winning of secondary copper

Krauss et al. (1999) give a picture of imports of copper and copper concentrate to Germany. This mix is used in this study as proxy for Europe.

### 5.4.1 Production process and infrastructure

Secondary copper consists of various types of scrap. Prompt scrap is directly reused in foundries and is not further processed. Old scrap has to be treated in a secondary copper smelter, where a variety of metal values are recuperated. Depending on the chemical composition, the raw materials of a secondary copper smelter are processed in different types of furnaces, including:

- blast furnaces (up to 30% of Cu in the average charge),
- converters (about 75% Cu), and
- anode furnaces (about 95% Cu).

A scheme of the process considered is given in Fig. 5.10. The blast furnace metal (“black copper”) is treated in a converter; then, the converter metal is refined in an anode furnace. In each step additional raw material with corresponding copper content is added. In the blast furnace, a mixture of raw materials, iron scrap, limestone and sand as well as coke is charged at the top. Air that can be enriched with oxygen is blown through the tuyeres. The coke is burnt and the charge materials are smelted under reducing conditions. Black copper and slag are discharged from tapholes (EEA (1999)).

The converters used in primary copper smelting, working on mattes containing iron sulphide, generate surplus heat and additions of scrap copper are often used to control the temperature. The converter provides a convenient and cheap form of scrap treatment, but often with only moderately efficient gas cleaning. Alternatively, hydrometallurgical treatment of scrap, using ammonia leaching, yields to solutions which can be reduced by hydrogen to obtain copper powder (EEA (1999)).

Alternatively, these solutions can be treated by solvent extraction to produce feed to a copper-winning cell.

Converter copper is charged together with copper raw materials in anode furnace operation. For smelting the charge, oil or coal dust is used, mainly in reverberatory furnaces. After smelting, air is blown on the bath to oxidise the remaining impurities.

Leaded brasses, containing as much as 3% of lead, are widely used in various applications and recycling of their scrap waste is an important activity. Such scrap contains usually much swarf and turnings coated with lubricant and cutting oils. Copper-containing cables and motors contain plastic or rubber insulants, varnishes, and lacquers. In such cases, scrap needs pre-treatment to remove these non-metallic materials. The smaller sizes of scrap can be pre-treated thermally in a rotary kiln provided with an after-burner to consume smoke and oil vapours (so-called Intal process). There are also various techniques available to remove rubber and plastic insulations of electric cables.

### 5.4.2 Emissions and waste

The stages used for secondary copper production are generally similar to those for primary production but the raw material is usually oxidic or metallic and process conditions are therefore varied. Other than in the primary copper production elevated levels of halogenated organic compounds may arise, such as TCDD. Slags are usually used in construction.

### 5.4.3 Winning of secondary copper in ecoinvent

This part is mainly based on Rentz et al. (1999), who described one single large plant. These values are added with Bruch et al. (1995).

The module describes the production of secondary copper in Germany as proxy for Europe. It is designed for the use of the metal as part of the supply mix “copper, at regional storage”. It is not to be used if the impact of the secondary copper is expected to be considerable in a LCA study. In such cases, a more detailed analysis has to be conducted.

The modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.11 and Fig. 5.12. Ecoinvent meta information for this process is summarised in Tab. 5.1 on page 17 ff.

The values for material input and output was taken from Rentz et al. (1999), which describe the worlds biggest plant for secondary production (Hüttenwerke Kayser AG, GER). No allocation to other by-products like copper sulphate has been considered, but the whole ecological burden is attributed to the main product secondary copper cathodes. Electricity demand for electrolysis was taken from Bruch et al. (1995), whose fossil energy demand for smelting (9.21 GJ / t Cu) is similar to this used in this study (overall 9.1 GJ / t Cu). Copper scrap was modelled with a proxy module for the collection and handling of iron scrap. Since scrap does not count as resource according to ecoinvent cut-off rule – i. e. no inventory entry –, the different scrap origin (iron instead of copper) does not play a role. About 10 % of blister copper is used from primary copper production into secondary production.

Emissions were taken from Rentz et al. (1999) and added with values reported in EEA (1999) (Tab. 5.12 and Tab. 5.13). Effluent volume was mentioned in Bruch et al. (1995) with 1 m<sup>3</sup> / t Cu. This volume is represented in the dataset as “treatment of clean waste water”, thus no emissions to water are inventoried. The emissions into water – i. e. after waste water treatment – are accounted for in the this dataset as direct emissions. The specific emission factor for TCDD (50 µg / t Cu) was reported in EC (2002).

#### Data quality

The overall quality is sufficient for the use proposed. But poor data exist for collection and beneficiation of old scrap and no data on leaching agents and emissions from Hydrolytic processes were available. However, the bias should be negligible because of high level of throughputs and energy demand.

Fig. 5.10 Secondary copper production. Process scheme after Rentz et al. (1999). Scheme relates to the plant “Hüttenwerke Kayser AG”, Germany.

Tab. 5.12 Secondary copper production. Emissions to air from two different sources (EEA (1999) and Rentz et al. (1999)); the last column shows the value chosen in this study.

Fig. 5.12 Flows for “copper, secondary, at refinery” (outputs) and its representation in the ecoinvent database. Values correspond to the functional unit of 1 kg copper.

## 5.5 Copper, at regional storage

### 5.5.1 Copper, from imported concentrates, at refinery in ecoinvent

This module is identical to “Copper, primary, at refinery, RER” but without neither any input of copper concentrate, nor any input of SX-EW copper. In this way it can be used to be combined with imported concentrates, whose production – mining and beneficiation – otherwise would be counted double.

### 5.5.2 Copper, at regional storage in ecoinvent

This module is based on information on the origin and type of imported copper for Germany in 1994 cited in Krauss et al. (1999). The layout relates to Fig. 5.2.

The module characterises the copper supply in Germany in 1994. It is designed for the use of the metal in various technical applications such as alloys and construction material in European production processes.

The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.13. Ecoinvent meta information for this process is summarised in Tab. 5.1 on page 17 ff.

Data on the amount and origin of the imported primary copper and concentrate is given in Tab. 5.14 and Tab. 5.15, from which the transport service in tkm results. Krauss et al. (1999) estimate the secondary copper use with 650'000 t in 1994, where 50% went directly into the foundries and 50% into the secondary copper production.

For copper and concentrate supplied by countries with no specification of the origin (“other”), the respective modules for South America is used, but for transport distance the resulting mean distance from RER, RLA, and ID has been chosen.

For prompt scrap, which is used directly in the foundries, the respective module for collection and handling of iron scrap has been chosen as proxy.

#### Data quality

The overall quality of this module is fair, depending on accuracy of the consumption values. The system of copper production in its different pathways is far more complex than pictured in this study. A more comprehensive approach as shown in Bertram et al. (2002) may enhance the quality of the data.

**Tab. 5.14 Import of copper concentrate to Germany in 1994. In the last column values for transport service in tonnes and kilometres (tkm) are given (Krauss et al. (1999)). Per kg “copper, from imported concentrates” (=13.1% in the supplier mix “copper, at regional storage”) 3.38 kg concentrates in average are required (=0.441 kg concentrates per kg “copper, at regional storage”).**

| Origin      | RER      | RLA      | ID       | other    | total        | Per kg concentrate |
|-------------|----------|----------|----------|----------|--------------|--------------------|
| concentrate | 197669 t | 206235 t | 164316 t | 84612 t  | 652832 t     | 1 kg               |
| ship sea    | 2750 km  | 14268 km | 18800 km | 11939 km | 7.59E+09 tkm | 11.62 tkm          |
| ship river  |          | 412 km   |          | 412 km   | 1.20E+08 tkm | 0.184 tkm          |
| train       | 190 km   |          |          | 190 km   | 5.36E+07 tkm | 0.082 tkm          |
| lorry       | 45 km    | 310 km   | 10 km    | 122 km   | 8.48E+07 tkm | 0.13 tkm           |

**Tab. 5.15** Import of primary copper (=56% in “copper, at regional storage”) to Germany in 1994. In the last column values for transport service in tonnes and kilometres (tkm) are given (Krauss et al. (1999)).

| Origin     | RER      | RLA      | ID       | other    | imported | total        | Per kg Primary | Per kg mix |
|------------|----------|----------|----------|----------|----------|--------------|----------------|------------|
| copper     | 353281 t | 111078 t | 32584 t  | 138979 t | 193000 t | 635922 t     | 1 kg           | 0.56 kg    |
| ship sea   | 3071 km  | 14100 km | 20000 km | 12390 km |          | 5.02E+09 tkm | 6.06 tkm       | 3.40 tkm   |
| ship river | 87 km    |          |          | 87 km    |          | 4.28E+07 tkm | 0.052 tkm      | 0.029 tkm  |
| train      | 2000 km  | 550 km   | 1050 km  | 1200 km  | 200 km   | 1.01E+09 tkm | 1.22 tkm       | 0.681 tkm  |
| lorry      | 15 km    | 200 km   |          | 108 km   | 100 km   | 6.18E+07 tkm | 0.075 tkm      | 0.042 tkm  |

**Tab. 5.16** Copper supply in the European region and the resulting fractions in the supply dataset “copper, at regional storage, RER” (column “% of total”). Copper supply from imported concentrates means that the copper is produced within Europe (Germany being reference region) from concentrates that are extracted elsewhere (see Tab. 5.17).

| Copper supply              | primary Copper | secondary copper | % of primary | % of total |
|----------------------------|----------------|------------------|--------------|------------|
| RER                        | 353281 t       |                  | 43%          | 23.9%      |
| RLA                        | 111078 t       |                  | 13%          | 7.51%      |
| ID                         | 32584 t        |                  | 4%           | 2.20%      |
| Other                      | 138979 t       |                  | 17%          | 9.40%      |
| from imported concentrates | 193000 t       |                  | 23%          | 13.1%      |

Fig. 5.13 Flows for “copper, at regional storage” and its representation in the ecoinvent database. Values correspond to the functional unit of 1 kg copper.

## 5.6 Copper alloys: brass bronze and brazing solders

From the multitude of different copper alloys the two most important are modelled as brass and bronze:

- Brass in ecoinvent is cartridge brass (70/30 brass, C26000) composed of 70% (w/w) copper and 30% (w/w) zinc.
- Bronze in ecoinvent is CuSn4 (C51000) composed of 94.97% (w/w) Cu, 5% (w/w) Sn and 0.03% (w/w) P.

From the multitude of brazing solders the general purpose cadmium-free solders are often used. In this class, the CuZn40 is an important material that is chosen as "typical" brazing solder in this study.

Production of copper alloys is basically done by melting the different metals and casting of ingots. No specific data are available for the processes. It is assumed that due to the high vapour pressure of zinc and tin, parts of these inputs arise as air emissions. It is further assumed that filters are commonly used to abate these emissions. The filter dust containing mainly zinc or tin is assumed to be recycled.

The casting of brass and bronze to the final form needs the moulds and energy for melting the alloy. Moulds are either made of metal (steel) or of sand.

### 5.6.1 Copper alloy production in ecoinvent

The three modules "brass, at plant", "bronze, at plant", and "brazing solder, cadmium free, at plant" include the material and energy inputs for melting the metals. The energy is calculated using the heat capacity and the enthalpy of fusion of the constituents (see Tab. 5.18). A mix of 50% natural gas, 40% heavy fuel oil, and 10% electricity is assumed for the heat production. A metal loss of 1% is assumed. This metal is recycled.

Tin and zinc emissions to air (after abatement) are assumed 0.1% (w/w) of the respective input.

The standard distances according to Frischknecht et al. (2003) for the transportation of the metal inputs are used.

The infrastructure is approximated by the infrastructure for aluminium casting. Thereby it is assumed that the amount of infrastructure corresponds to the volume of material throughput and thus is recalculated according to the different densities of aluminium and copper alloys.

The ecoinvent meta-information for the copper alloy production is given in Tab. 5.19 and the in- and output flows for "brass, at plant", "bronze, at plant", and "brazing solder, cadmium free, at plant" are given in Fig. 5.14, Fig. 5.15 and Fig. 5.16 respectively. Those for "casting, brass" and "casting, bronze" are given in Fig. 5.17 and Fig. 5.18 respectively.

Tab. 5.18 Calculation of energy consumption for brass and bronze production

|                                           | Copper | Zinc  | Tin   | Brass | Bronze | Solder | Unit     | Source             |

1 10% heat loss during heating and melting assumed

2 including 10% material loss for brass, bronze and solder

### 5.6.2 Data quality

Data uncertainty is derived using the Pedigree matrix as described in (Frischknecht et al. (2003)).

All data for the brass and bronze production are assumptions based on qualitative information and theoretical models. Thus uncertainty is rather high. These data are of insufficient quality for LCA where these metals play an important role.

| General Comment to reference function | Stands for brass with 70% Cu and 30% Zn. All data are calculated based on assumptions and theoretical models. Their overall quality is poor. | Stands for bronze with 95% Cu and 5% Sn. All data are calculated based on assumptions and theoretical models. Their overall quality is poor. | Stands for solder with 60% Cu and 40% Zn. All data are calculated based on assumptions and theoretical models. Their overall quality is poor. |

## 5.7 Telluride and Silver containing slime as by-product

The chief source of tellurium is a by-product of electrolytic copper refining, where it concentrates into the anode slimes. This source accounts for over 90% of the supply, although tellurium is also recovered from the flue dusts and gases generated during the smelting of copper, bismuth and lead ores, and from lead refinery skimmings<sup>9</sup>.

Like tellurium, also silver accumulates in the anode slimes. Different sources report that the share of silver from copper extraction declined from around 30% in 1996 to 25% today (JMB (2002); Klapwijk et al. (2006); Renner et al. (2002)).

Since the composition of the arising slimes chiefly depends on the composition of the copper anodes, the content of silver and tellurium varies considerably (Tab. 5.20).

**Tab. 5.20** Characterisation of different anode slimes. Numbers are in %wt; span relates to reported minimal – maximal values; the mean value in Cooper (1990) is the median of the reported operations (n=18).

| Operations               | Ag                 | Te             | Se                | Cu                 | Source                 |

### 5.7.1 Anode slime generation in ecoinvent

The multi-output-process "anode slime generation, primary copper production" delivers the co-products "anode slime, silver and tellurium containing, primary copper production" and "cathode, copper, primary copper production". The product "cathode, ..." is an intermediary in the production of refined copper and is not to be used by the LCA practitioner. The flow "anode slime, ..." is a by-product of this process that receives part of the burdens allocated.. (Fig. 5.19).

The modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.20. The ecoinvent meta information for this process is summarised in Tab. 5.21.

**Fig. 5.19** Process layout of the anode slime generation and its relation to other processes in ecoinvent.

Both reference flows are intended to be used as raw material in the production of the respective metals. For further information on process and inventory of the refined metals refer to the respective Parts within this report.

Based on anode slime compositions listed in Tab. 5.20, the anode slime is assumed to contain 20% residual copper, 20% silver and 3% tellurium. The nominal generation of this anode slime is harmonised with the world production average over the last three years (Tab. 2.4). Considering that 25% of silver (4'875 t/a average from 2004-2006) and 95% of tellurium (107.6 t/a average from 2004-2006) were supplied by the copper industry, 326 g refined silver and 7 g refined tellurium are produced per tonne copper that is extracted (Tab. 5.22). Given an extraction efficiency of 100% for silver (closed cycle) the amount of 1.63 kg anode slime (20% silver) per tonne cathode copper produced is calculated. Taking the Te content of 3% in the slime, 49 g Te per tonne copper extracted would then be co-extracted on a global average. However, this 49 g/t contrast with the 7 g/t Te that are estimated with a top-down calculation basing on mine production figures. This mismatch between bottom-up and top-down calculation can be explained by the fact, that in many cases the rarer but jointly extracted metals such as Tellurium are completely recovered on a global average. Many operations do not recover Tellurium at all. A second reason may be found in the limited extraction efficiency when leaching tellurium.

However, the allocation of the upstream burden from the copper production – which determines this inventory – is allocated by means of the effective produced amount of silver and tellurium from this source (top-down figures). Therefore the uncertainty about slime composition and completeness of the recovery of the resources in the ground do not affect this inventory model but the amount of silver and tellurium resources required (input flows from nature).

The upstream burden is reflected by the production of one kg copper on a global average; the associated burdens are allocated to the reference flows by their value. The elementary flows that represent

the depletion of the resource itself for tellurium and silver are introduced using the same extraction yields as for copper, since the metals are incorporated in the same mineral particles.

**Tab. 5.22 Production factors for the by-products silver and tellurium from copper production, three years average (USGS (2007)).**

| Year | Copper mine production, tpa | Silver from copper, tpa | Tellurium from copper, tpa | Silver per copper, t / t | Tellurium per copper, t / t |
|------|-----------------------------|-------------------------|----------------------------|--------------------------|-----------------------------|
| 2004 | 14'600'000                  | 4'925                   | 88.065                     | 3.37E-04                 | 6.03E-06                    |
| 2005 | 15'000'000                  | 4'825                   | 113.05                     | 3.22E-04                 | 7.54E-06                    |

| mean | 14'966'667                  | 4'875                   | 107.6                      | 3.26E-04                 | 7.17E-06                    |

### 5.7.2 Allocation and resource correction

The allocation split is done by the value represented by the reference flows “cathode copper” and “anode slime”. Since the anode slime has no market price as such, it is assessed by the marginal profit that is assumed to be in the order of the overall operations profit. A value of 10% of the price of the refined commodity (telluride and silver) has been chosen.

As explained in the preceding section the value of the anode slime is measured in the effective amount of silver and tellurium that is produced on a global average, including the extraction losses from the point where silver or tellurium is being extracted, i.e. CuTe precipitate. Therefore, and in accordance with Tab. 5.22, it is assumed that 326 g Ag and 7.97 g Te per tonne produced copper cathode are effectively extracted, assuming a closed-loop situation for silver (recycling the electrolyte to the process) and 90% for the preparation of CuTe as precipitate. The proceeds for refined silver and tellurium are at 269 \$/kg and 151 \$/kg (Tab. 5.23).

With this approach an internal value of 5.45 \$ per kg anode slime and 4.48 \$ per kg cathode copper and a respective allocation split of 0.2% of the burden to the 1.63 g of anode slime and the remaining 99.8% of the burden to the 1 kg of cathode copper.

Part of the copper resource that is represented by the upstream inventory for copper production is allocated by the economic procedure to the anode slime and has to be corrected.

The depletion of silver (326 g) and tellurium (49 g) per tonne of copper extracted is not accounted for in the upstream processes represented by the copper production. They therefore have to be introduced and are allocated fully to the anode slime.

Per kg copper produced, 1.12 kg copper resource is depleted. According to the allocation split 0.20% of this amount or 2.22E-3 kg is attributed to the anode slime and has to be subtracted and re-allocated to the cathode copper produced.

**Tab. 5.23** Average market price for copper (LME), silver and tellurium in \$ per tonne. Data compiled after USGS (2003) through 2004 and USGS (2007) for 2005/6.

### 5.7.3 Data quality

This inventory is mainly based on theoretical considerations to reflect the upstream burden and resources depletion in order to allocate them to the reference flow of anode slime. High uncertainties in the amount and allocation split are assumed.

## 5.8 Molybdenum

Molybdenite is the starting material for molybdenum trioxide and ferromolybdenum, which is the raw material for alloying steels with molybdenum. Since molybdenite is almost exclusively won from porphyry deposits, its production process is related to the exploitation of copper ores. Secondary porphyry deposits bear lower concentrations of molybdenum, in this case it is won only as co-product in the copper production (see Section 2.2 Primary Molybdenum on page 7). Molybdenum from co-production is modelled as co-product in Section 5.2 Winning primary copper. The ecological burden is distributed between molybdenite and copper concentrate according to their revenue (price times production).

According to the scheme in Fig. 5.1 a separate module for the exploitation of molybdenite as main product is necessary as well as a production mix module for molybdenite. These two modules are discussed in the following sections.

### 5.8.1 Exploitation of molybdenite in ecoinvent

The module describes the exploitation of molybdenite as main product. It is based entirely on the related process mining of copper ore. It is designed solely as part of a production mix. The multioutput-process “mining of molybdenite” delivers the two co-products “molybdenite concentrate, main product” and “copper, concentrate, coupleproduction Mo”.

The ecoinvent meta information for this process is summarised in Tab. 5.1 on page 17 ff.

The primary porphyry deposits are richest in molybdenum and are exploited for its molybdenum values. Hence the attribution of the ecological burden is different, since copper concentrate now is the by-product. Beside of the different resource demanded and the consequently different output of molybdenite – relating to the higher Mo content (0.041% in crude ore) – no other differences with respect to the Module “mining copper ore” (GLO) exist. Details are discussed in chapter 5.1 of this study.

#### Allocation

The ecological burden of the molybdenite mining is distributed among the coupled products copper concentrate and molybdenite concentrate. As allocation procedure the revenue is chosen. With a price of US\$ 5.75 per kg Mo (USGS (2003)) this gives a revenue of US\$ 3190 per tonne molybdenite concentrate with an assumed composition of 92.5% MoS<sub>2</sub>. Copper concentrate is traded in large quantities. However, the price of copper concentrate could not yet be assessed; it is estimated with the final bids of three auctions held in 2000 on an online web-auction<sup>10</sup> resulting in an average price of 15.3 US cents payable for refining and smelting per pound copper. With a copper price of 0.95 US\$/kg, a price of 522 US\$ per tonne of concentrate with 29.7% copper content is calculated. These assumptions and a production ratio of 74 kg molybdenite concentrate per 3.5 t copper concentrate lead to an average revenue of 236 US\$ and 1816 US\$ per tonne molybdenite and copper contained in the ore, respectively, – with the metallurgical yield included – and to an allocation factor of 11% and 89% for molybdenite and copper concentrate, respectively.

#### Data quality

The same constraints apply like for the module “mining of copper ore”. The assessment will highly vary with the price of copper concentrate and molybdenite. The yield of molybdenite is not evident; it is merely estimated based on the content of molybdenum in the ore.

### 5.8.2 Molybdenite, at plant in ecoinvent

The module describes the production mix composed of molybdenite from coupled production in copper industry and molybdenite as main product.

Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 17 ff.

Within the world-wide production of molybdenite a share of 58% originates from co-production in the copper industry, 42% originate from primary deposits. The molybdenite from scheelite leaching in the tungsten production is neglected in this study. Since molybdenite is a intermediary product, it is modelled as production mix, i.e. no transportation and energy use for the distribution is included in this module. Molybdenite from co-production is inventoried as “Molybdenum, molybdenite concentrate, couple-production Cu”, the main product molybdenite as “Molybdenum, molybdenite concentrate, main product”.

For the subsequent production of molybdenum oxide and later ferromolybdenum, transportation to the manufacturing plants and transport of the finished product to the user has to be considered.

#### Data quality

The main constraints in this module are missing information on the production process. The choice of copper production as proxy is a strong simplification. The overall assessment will highly vary with share – molybdenum as main- or by-product – and price of copper concentrate and molybdenite.

### 5.8.3 Molybdenum, at regional storage in ecoinvent

Molybdenum is produced from molybdenite by roasting to  $\text{MoO}_3$  and subsequent metallurgical steps. No process specific data for these steps have been found. Thus the roasting and metallurgical processes from the zinc production are used as a proxy. The concentrate of zinc and molybdenite are both sulphidic and the metal concentration is similar. Thus the inventory for the production of 1 kg "zinc, at regional storage" is used directly for describing the production of 1 kg molybdenum. To adjust the concentrate input, the amount of zinc concentrate that is needed in the production of zinc is subtracted and the molybdenite concentrate therefore inventoried. The amount of molybdenite concentrate is calculated assuming the same yield as for zinc concentrate to zinc. It is slightly lower than the amount of zinc concentrate, because the metal concentration is slightly higher (55% Mo vs. 53% Zn).

The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.21. The ecoinvent meta information for this process is summarised in Tab. 5.1 (page 17 ff).

#### Data quality

The very crude approximation of the previously described production of molybdenum with data from another metal implies a poor data quality. The data set must only be used if the relevance of molybdenum is low in a LCA study. If the focus of such a study would lie on molybdenum, the process would need to be further investigated.

EMPA Dübendorf, Swiss Centre for Life Cycle Inventories, Dübendorf, CH, Online-Version under: [www.ecoinvent.ch](http://www.ecoinvent.ch).

## Comments on version 2.1

This part corresponds to the original report in Althaus et al. (2004) that has been updated with the changes reported in Frischknecht et al. (2006). The changes were implemented with v1.3 and affect mainly the amount of added lime and the herewith related emissions of carbon dioxide in the metallurgical step.

The amount of limestone input in the Ferronickel-Dataset was increased by factor 4. The CO<sub>2</sub> emission related to limestone decomposition in MO-Process (#35) is decreased a factor 16. The allocation factors applied on this emission (Values v1.2: 8.46% on Copper / 91.54% on Nickel) are corrected to 14% on Copper / 86% on Nickel. Further more. The amount of sulphidic tailings disposed in the MO-Process increased by 2/3.

In Version 2.1, the representation of part of the electricity input into the Ferronickel-dataset was corrected from UCTE mix to hydropower.

Chapter “6 Cumulative Results and Interpretation” of the original report has been deleted for the current update.

## Summary

The primary nickel and ferronickel production is modelled for the global situation.

Nickel is co-produced with Copper and the model is made accordingly. Allocation is made by revenue.

For a lack of data the secondary nickel production could not be inventoried. However, since most of the nickel is used in alloys it is not recycled separately but with the alloyed steel.

Mining, beneficiation and the different metallurgical processes are inventoried vertically aggregated because of difficulties to clearly allocate some of the flows to one single step and because the intermediate steps would not make sense in another context. The Figures in this report however contain the available information to the single steps.

# 1 Introduction

This chapter describes the production of Nickel from cradle to consumer in Europe. Inventory data is taken mainly from (Hilbrans & Hinrichs (1999)) together with background data from IPPC (2002) and IPPC (2001). Market data on nickel and copper are provided by the London Metal Exchange<sup>1</sup>.

Since nickel always is associated with other metals, the production yields a fraction of other metals than nickel, mainly copper (Cu), cobalt (Co) and platinum group metals. The process of primary production described in this chapter is formally a multioutput-process with the coupled products Ni and Cu. This makes it necessary to allocate the inventory to these products. The demand for nickel-containing ore is allocated by mass. The rest of the inventory is allocated by revenue. The coupled production of cobalt is neglected because due to a lack of data no meaningful allocation factors could be established.

Known annual world production capacity of primary nickel products in the early 1990s was approximately 1240 kilotonnes, 485 of which were in former Soviet and East Bloc countries. In recent years, annual world production has averaged in excess of 900 kilotonnes. Primary nickel products fall broadly into two categories - Class I and Class II. Class I products contain at least 99.8% nickel whilst all other primary nickel products are Class II. Unlike Class I products, Class II products range widely in nickel content.

## 2 Reserves and Resources of Nickel

Metals are a special class of materials. They are not consumed but rather used during a product life cycle. When recovered the properties are theoretically identical. The metal can be re-used in another product life cycle, provided that its concentration makes a recovery profitable. The recovered metal is referred to as secondary metal, whereas the metal originating directly from the ore is referred to as primary metal. In LCIs these two types – primary and secondary metal – are often differentiated because they bear a different ecological burden.

Since nickel is used in ecoinvent as intermediate product in different metal manufacturing industries, no secondary production is covered in this report. Secondary nickel is consumed directly in the form of re-melted scrap and other recycled products generally in the production of ferro-nickel and stainless steel. Other secondary materials such as catalysts and precipitator dusts are recovered in the primary smelting processes, usually in the slag furnace.

Nickel ores can be classified in a sulphidic type and an oxidic type. An overview over the different nickel bearing ores is given in Tab. 2.1, the composition of some ores in Tab. 2.2. Although 80 % of the world's known nickel resources on land are in oxide ore bodies, only 40 % of nickel production comes from this source. The greater part of the nickel produced is recovered from sulphide ores. The nickel content of sulphide ores can be concentrated relatively easily and cheaply by physical methods, while oxide ores must be treated in bulk. The potential for recovering the more numerous and valuable co-products also favours the exploitation of sulphide ore. However, the grades of sulphide ores are continually declining as the richer ores are consumed, and the cost of underground mining, particularly labour costs, is continually increasing. Inevitably therefore, oxide ore bodies, which are all relatively uniform in grade and can be surface mined, must in future support a larger share of nickel production (Kerfoot (1997)).

A detailed overview over the global factory production and a statistic on US use and production of nickel is available in the online version of the USGS “Mineral Commodity Summary” (USGS (2003)). The world-wide mine production by country in 2002 and the estimated reserves is listed in Tab. 2.3.

### 2.1 Sulfidic Ores

Sulphide nickel ores consist principally of nickeliferous pyrrhotite ( $\text{Fe}_7\text{S}_8$ ), pentlandite ( $(\text{Ni}, \text{Fe})_9\text{S}_8$ ), and chalcopyrite ( $\text{CuFeS}_2$ ). Pentlandite, the commonest of the sulphide minerals, probably accounts for 60 % of world nickel production. Nickeliferous pyrrhotite is normally the most abundant phase in a nickel ore. It contains nickel in solid solution (0.2 – 0.5 % Ni) in addition to very finely divided pentlandite inclusions. Chalcopyrite is the most important copper mineral, although cubanite is often present in lesser amounts. Sulphide ores typically grade 0.4 – 2.0 % nickel, 0.2 – 2.0 % copper, 10 – 30 % iron, and 5 – 20 % sulphur. The balance consists of silica, magnesia, alumina, and calcium oxide.

Although the major minerals are the same in all large sulphide ore bodies, the relative amounts of pyrrhotite, pentlandite, and chalcopyrite vary widely. The relative amounts of the three minerals largely determine the choice of processing route. In addition to nickel production, a large number of valuable co-products can be recovered from sulphide ores, including copper, cobalt, the platinum group metals, gold, silver, selenium, tellurium, sulphur, and iron. Cobalt occurs principally in solid solution in pentlandite, at concentrations ranging from 1 to 5 % of the nickel content.

Major sulphide ore bodies occur in Canada, the Soviet Union, the Republic of South Africa, Australia, Zimbabwe, and Finland. According to (Hilbrans & Hinrichs (1999)) 62 % of the world nickel production originates from sulfidic ore in 1994.

## 2.2 Laterite Ores: Limonite and Silicate

The oxidic ores of nickel are formed by a chemical concentration process that occurs as a result of the lateritic weathering of peridotite rock. The dissolved nickel and magnesium, and the colloidal silica, percolate downwards in the laterite deposit, where they precipitate as hydrated silicates.

Some of the nickel may in fact remain in the upper layer, which is thus enriched in iron and nickel, but depleted in magnesium and silica. Such material, consisting mainly of ferric oxide minerals, is described as limonitic. This type of ore is typically relatively rich in cobalt and chromium. By contrast, in the silicate minerals, the separation of iron and nickel is more complete, and the nickel is present in silicate minerals with high magnesia content. Both types of material are almost always found in a laterite deposit, but in widely differing proportions.

Oxide nickel mineral deposits are currently exploited in Australia, Brazil, Cuba, the Dominican Republic, Greece, Indonesia, the Philippines, New Caledonia, Yugoslavia, the United States, and the Soviet Union. The laterite deposits in Oregon and California were formed when the climate was sub-tropical in past geologic epochs.

Tab. 2.1 Principal nickel minerals (Kerfoot (1997)).

| Mineral                     | Ideal formula                                                 | Nickel content, % |

## 3 Characterisation of the materials

Nickel is rarely used without further processing. Nickel is marketed solely on the basis of its chemical composition and according to its chemical purity as either a Class I or a Class II product. Typical compositions for Class I and II products are given in Tab. 3.2.

Class I includes the high-purity products, electrolytic cathode, carbonyl refined granules and powder, and hydrogen-reduced nickel in powder or briquette form.

Class II includes the various grades of ferronickel, nickel oxide, and metallised nickel oxide. In this study only ferronickel is of significance because of its use in the manufacturing of alloy steel and stainless steel.

However, Class I and Class II are intermediate market products. Most of it is used for alloying other metals. Stainless steels are particularly valued for their hygienic properties in hospitals and kitchens. In some applications, such as jet engines, nickel alloys are essential and cannot be substituted with other materials.

Inecoinvent only the intermediate nickel products “Class I Nickel” and “Ferronickel” are of importance. They are asked in the steel manufacturing and production of other alloys.

The reported effects of nickel and its compounds on humans are wide ranging, comprising effects that are both beneficial - the probable essentiality of nickel in humans - as well as harmful - skin allergy and, in certain circumstances, respiratory cancer (NIDIS (2003)).

Health Effects include

- Allergy of the skin to nickel - resulting in dermatitis. The following image shows a case of nickel eczema (dermatitis).
- Allergy of the lung to nickel - resulting in asthma
- In certain circumstances of exposure in refining, there may be a risk of cancer of the paranasal sinuses (close to the nose) and of cancer of the lung. This risk has now probably been completely removed in most modern plants.
- Nickel tetracarbonyl - an intermediate in the Mond process for refining nickel is very toxic to the lungs and heart.

### 3.1 Class I Nickel

Commercial nickel of this class (CAS 7440-02-0) is normally 99.7 % pure or better. Synonyms are “unwrought nickel, not alloyed”. Nickel is a silver-white metal. Factors that make nickel and its alloys commercially valuable commodities include strength, corrosion resistance, high ductility, good thermal and electrical conductivity, magnetic characteristics (below 340 °C) and catalytic properties. Some physical properties of pure nickel are given in Tab. 3.1. Nickel is not tarnished by air and is resistant to fluorine (F<sub>2</sub>) but is attacked by acids (except conc. HNO<sub>3</sub>). Class I nickel is marketed as cathodes, granules, powder, briquettes and rounds.

Tab. 3.1 Some physical properties of pure nickel (Kerfoot (1997)).

| property                                                   | value                                   |
|------------------------------------------------------------|-----------------------------------------|
| Melting Point (mp)                                         | 1455°C (1728 K)                         |

## 3.2 Ferronickel

Ferronickel (CAS 11133-76-9) is a market product of the nickel industry. It consists of an alloy of iron with nickel, with a nickel content of 20 - 50 % (Tab. 3.2). It is used in the manufacturing of stainless steels.

Tab. 3.2 Commercial forms of nickel (Kerfoot (1997)).

| Type             | Composition, % |                    |       |        |         |        |       |
|------------------|----------------|--------------------|-------|--------|---------|--------|-------|
|                  | Ni             | Co                 | Cu    | Fe     | C       | S      | O     |

## 4 Use / Application of Material

Unlike other non-ferrous metals, nickel is rarely used by itself but is commonly mixed with other metals to produce alloys. There are many different alloys containing nickel, each providing a particular combination of technical properties (corrosion resistance, mechanical properties and service life). Thus the two forms of nickel – class I nickel and ferronickel – are to high degree intermediate products for the metal industry.

**Tab. 4.1 Production of different nickel products (USGS (2003)).**

|              | 2000    |     |
|--------------|---------|-----|
| Ferronickel  | 220000  | 20% |
| Metal        | 638000  | 57% |
| Oxide sinter | 98200   | 9%  |
| Chemicals    | 18000   | 2%  |
| Unspecified  | 143000  | 13% |
| Total        | 1117200 |     |

More than 80 % of primary nickel is consumed in some 3'000 different alloys, grouped generally as stainless steels, alloy steels, and non-ferrous alloys. About 65 % of primary nickel is used in stainless steels alone, as shown in Fig. 4.1.

**Fig. 4.1 Uses of nickel in different industries. Source: NiDI<sup>2</sup>, 1996**

Electroplating accounts for roughly 10 % of primary nickel consumption, with the balance consumed by foundries and a host of other uses including chemicals, catalysts, batteries, welding rods, coinage, pigments for enamels/glasses/ceramics, electronics, and printing inks.

Most of the plating, foundry and "other" applications are "end-uses" of nickel; that is to say, the products are used directly by the customer or "end-user". Steels and other nickel alloys, on the other hand, are "intermediate" products that must be further processed or "transformed" into end-use commercial products in a number of industrial applications. These applications are shown in Fig. 4.2.

The major end-use sectors for nickel shown in Fig. 4.2 reflect various applications for the many of known nickel alloys as well as the direct use of primary nickel for electroplated and other products noted above. The use therefore can be diverted into an intermediate use in the form of metallic nickel (class I) and Ferronickel and into the end-use as nickel alloys.

<sup>2</sup> Nickel Development Institute, <http://www.nidi.org/>, accessed at 01. 03. 2003.

Fig. 4.2 Application of nickel Source: NiDl<sup>3</sup>, 1996

## 4.1 Nickel (class I)

Primary nickel metal powder is used in many applications including battery manufacture, coin production, welding products, fuel filters, brake linings, catalysts, cutting tools, paints, plastics, electronics, implants, and surface treatments by plasma spraying.

## 4.2 Ferronickel

Ferro-alloys are mainly used as master alloys in the iron and steel industry, because it is the most economic way to introduce an alloying element in the steel melt. Ferronickel in this case therefore is used as master alloy in the production of stainless steels. Further more it is used as starting materials in the preparation of chemicals and pure metal; as reducing agents (e.g., the use of ferrosilicon to reduce rich slag); as alloying elements in nonferrous alloys and as starting materials for special products such as amorphous metals.

## 4.3 Nickel Alloys

Nickel-bearing, "austenitic" stainless steels contain variable amounts of nickel, between 5 to 25 percent, and average about 10 % nickel. Commercial uses include chemical and food processing equipment, transportation equipment, structural claddings and other architectural applications, durable consumer goods such as cookware, and hospital and medical applications.

Nickel alloys can be hot or cold worked. Other processes include annealing, drawing, forging, spinning, and joining by soldering, brazing, gas welding, and resistance welding. Machining of most nickel alloys requires high-speed tools and flooding with cutting compounds.

---

<sup>3</sup> Nickel Development Institute, <http://www.nidi.org/>, accessed at 01. 03. 2003.

**Tab. 4.2 Some of the more common nickel alloys.**

| <b>Alloy</b>     | <b>Constituents</b>                                |
|------------------|----------------------------------------------------|
| Monel metals     | combinations of nickel and copper                  |
| Inconel metals   | nickel alloys containing chromium and iron         |
| Hastelloy metals | combinations of chromium, molybdenum and iron      |
| Illium nickels   | nickel alloys with chromium, molybdenum and copper |

Nickel alloy steels are used in heavy machinery manufacturing, armoured plate, tools, and high-temperature equipment including gas turbines and scrubbers. Non-ferrous alloys include nickel-copper alloys, typically containing about 65% nickel, and copper-nickel alloys, typically containing about 10% nickel, used extensively in desalination plants for converting seawater into fresh water. Ni-Cu/Cu-Ni alloys are also employed in marine equipment and inorganic acid and alkali handling equipment. Nickel-chromium alloys, containing approximately 40-70% nickel, are used in corrosive chemical environments and high-temperature applications such as heating elements and gas turbine aero-engine components. Nickel-copper-zinc alloys, including nickel silver with less than 18% nickel, are used for decorative purposes, including jewellery.

Different alloy types are used in specific applications. The constitution of some common nickel alloys is given in Tab. 4.2.

- Corrosion-resistant alloys: nickel, monel, hastelloy, illium, nirolium for use in chemical and process plant, plating coinage, food processing and water treatment.
- High temperature alloys: inconel, incoloy, nimonic, nimocast used for furnace components, boiler components, heat-treatment equipment, power generation, heat exchangers.
- Electrical Alloys: nickel, brightray, nichrome, constantan for use in ferry electronics, heating elements, industrial furnace elements, resistors, thermocouples and spark plugs.
- Magnetic Alloys: nickel, permalloy, mumetal used in magnetostrictive devices, magnetic shields, HF transformation, loading cells, transformer and rotor laminations, temperature compensators.
- Controlled-expansion and constant modulus alloys: invar, nile, ni-Span, elinvar, bimetals, thermostats, glass-sealing and weighing machines.
- Miscellaneous alloys: nitinol, hy-stor employed in shape-memory devices, hydrogen storage and brazing alloys.

## 5 System Characterisation

The winning of nickel can be classified in two main process chains as shown in Fig. 5.1. The first process chain represents the winning of nickel from sulphidic ore, yielding Class I Nickel as market product. This class of nickel is used in a wide range of applications. The other path represents the winning of ferronickel from lateritic ore.

The aim of this study is to inventory the two intermediate products “Nickel Class I” and “Ferronickel” as raw materials for nickel alloys. These two modules represent the most important application of nickel. The system boundaries are set at the production gate, both modules represent the production mix, no transport to the desired region of the application is included.

The meta information of the modules are summarised in Tab. 5.1.

**Fig. 5.1** Winning of nickel from ore to application. Two main process chains can be identified, the sulphidic path yielding Class I nickel and the lateritic path yielding ferronickel. Ferronickel is mainly used in the production of stainless steel, whereas Class I nickel is used in a wide range of applications.

**Tab. 5.1** Ecoinvent meta information for the processes for the production of Class I nickel and ferronickel.

| Included Processes                    | The module includes a mining and a beneficiation step with the mining and beneficiation infrastructure and disposal of overburden and tailings. Subsequently it includes the metallurgy step with the disposal of slag, the infrastructure and the separation of the co-product copper, and the refining step yielding the desired Class I nickel inclusively the metallurgical infrastructure. Production, application and emissions of most agents and additives used in beneficiation and metallurgy are also included.                                                                                                                                                                                                                                                                                                                                                                                         |

| Synonyms                              |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| General Comment to reference function | The module describes the global production mix for Class I nickel in 1994 with a coupled production of a certain amount of copper. The multioutput-process "nickel production, sulphidic ore, primary" delivers the co-products "nickel, 99.5%, at plant" and "copper, primary, coupleproduction nickel". It is designed for the use of the metal as intermediate product or as raw material in the plating industry or the manufacturing of stainless steels and alloys. It is not to be used if the impact of the Class I nickel is considered to be high. In such cases, a more detailed analysis depending on scope and allocation procedures has to be conducted. The data used is mainly based on a study of the energy and material streams resulting from the production of class I nickel. Lacking data mainly on direct process specific emissions were taken from similar processes for copper winning. |

| Geography text                        | This module represents a global production mix. Some processes like blasting, lime and energy production and transport originate from data sets valid for Switzerland or Europe.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| Technology text                       | Mining is done underground, followed by beneficiation through flotation where considerable amounts of agents and lime are added. Overburden and tailings are disposed on the mining site and partly re-filled. This module covers the five major production routes, aggregated according to their market share in 1994. Sulphur dioxide in the off-gas is recovered producing sulphuric acid. For electricity mix a mix of 60% hydropower and 40% electricity at grid was chosen.                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| Representativeness [%]                | 100                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |

| Data Set Version                      | 2.0                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| Included Processes                    | The module includes a mining and a beneficiation step with the mining infrastructure. Subsequently it includes the metallurgy step with the disposal of slag and the metallurgical infrastructure. Production, application and emissions of most agents and additives used in beneficiation and metallurgy are also included.                                                                                                                                                                                                                                             |

| General Comment to reference function | The module describes the global production mix for ferronickel in 1994. It is designed for the use of the metal as raw material in the manufacturing of stainless steels and alloys. It is not to be used if the impact of ferronickel is considered to be high. In such cases, a more detailed analysis has to be conducted. The data used is mainly based on a study of the energy and material streams resulting from the production of class I nickel. Lacking data mainly on direct process specific emissions were taken from similar processes for copper winning. |

| Geography text                        | This module represents a global production mix. Some processes like blasting, lime and energy production and transport originate from data sets valid for Switzerland or Europe.                                                                                                                                                                                                                                                                                                                                                                                          |
| Technology text                       | Mining is done in open cuts, followed by beneficiation with a simple mechanical separation. Overburden and tailings are disposed inside the mining panels. This module covers the major production route for ferronickel. For electricity mix a mix of 60% hydropower and 40% electricity at grid was chosen.                                                                                                                                                                                                                                                             |
| Representativeness [%]                | 80                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| Production Volume                     | 329'478 t nickel in lateritic raw ore in 1993                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| Sampling Procedure                    | literature                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| Extrapolations                        | see Geography and Technology                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| Uncertainty Adjustments               | none                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |

## 5.1 Winning of Class I Nickel

This part is mainly based on (Hilbrans & Hinrichs (1999)). General process description was taken from Kerfoot (1997). Allocation is done by revenue between the coupled products Nickel and Copper using the values of 6647\$ / t Nickel and 1986\$ / t Copper.

### 5.1.1 Production process and infrastructure

**Mining.** 95% of sulphidic nickel ores are mined underground in depths between 200m and 1800m, the ore is transferred to the beneficiation. Widening of the tunnels is mainly done by blasting. The overburden – material, which does not contain PGM-bearing ore – is deposited off-site and is partially re-filled into the tunnels.

**Beneficiation.** After mining, the ore is first ground. In a next step it is subjected to gravity concentration to separate the metallic particles from the PGM-bearing minerals. After this first concentration step, flotation is carried out to remove the gangue from the sulphidic minerals. For neutralisation lime is added. In the flotation several organic chemicals are used as collector, frother, activator, depressor and flocculant. Sometimes cyanide is used as depressant for pyrite. Tailings usually are led to tailing heaps or ponds. As a result, nickel concentrates containing 7 - 25% Ni are produced.

**Metallurgy.** There are many different process possibilities to win the metal. The chosen process depends on the composition of the ore, the local costs of energy carrier and the local legislation. Basically two different types can be distinguished: the hydrometallurgical and the pyrometallurgical process with a share of 6 % and 54 % of the worldwide nickel produced. An overview is given in Fig. 5.2.

**Fig. 5.2** Overview over some process possibilities for nickel winning. The chosen process depends on the composition of the ore, the local costs of energy carrier and the local legislation. Scheme from (IPPC (2001))

**Pyrometallurgy.** The pyrometallurgical treatment of nickel concentrates includes three types of unit operation: roasting, smelting, and converting. In the roasting step sulphur is driven off as sulphur dioxide and part of the iron is oxidised. In smelting, the roaster product is melted with a siliceous flux which combines with the oxidised iron to produce two immiscible phases, a liquid silicate slag which can be discarded, and a solution of molten sulphides which contains the metal values. In the converting operation on the sulphide melt, more sulphur is driven off as sulphur dioxide, and the remaining iron is oxidised and fluxed for removal as silicate slag, leaving a high-grade nickel – copper sulphide matte. In several modern operations the roasting step has been eliminated, and the nickel sulphide concentrate is treated directly in the smelter.

**Hydrometallurgy.** Several hydrometallurgical processes are in commercial operation for the treatment of nickel – copper mattes to produce separate nickel and copper products. In addition, the hydrometallurgical process developed by Sherritt Gordon in the early 1950s for the direct treatment of nickel sulphide concentrates, as an alternative to smelting, is still commercially viable and competitive, despite very significant improvements in the economics and energy efficiency of nickel smelting

technology. In a typical hydrometallurgical process, the concentrate or matte is first leached in a sulphate or chloride solution to dissolve nickel, cobalt, and some of the copper, while the sulphide is oxidised to insoluble elemental sulphur or soluble sulphate. Frequently, leaching is carried out in a two-stage countercurrent system so that the matte can be used to partially purify the solution, for example, by precipitating copper by cementation. In this way a nickel – copper matte can be treated in a two-stage leach process to produce a copper-free nickel sulphate or nickel chloride solution, and a leach residue enriched in copper.

**Refining.** In many applications, high-purity nickel is essential and Class I nickel products, which include electrolytic cathode, carbonyl powder, and hydrogen-reduced powder, are made by a variety of refining processes.

The carbonyl refining process uses the property of nickel to form volatile nickel-carbonyl compounds from which elemental nickel subsides to form granules. Electrolytic nickel refineries treat cast raw nickel anodes in a electrolyte. Under current the anode dissolves and pure nickel deposits on the cathode. This electrolytic refining process is obsolete because of high energy demand and the necessity of building the crude nickel anode by reduction with coke. It is still practised in Russia. Most refineries recover electrolytic nickel by direct electrowinning from purified solutions produced by the leaching of nickel or nickel – copper mattes. Some companies recover refined nickel powder from purified ammoniacal solution by reduction with hydrogen.

The multitude of processing possibilities was reduced in (Hilbrans & Hinrichs (1999)) to five major process routes for nickel winning from sulphidic ores. Their layout is given in Tab. 5.2. This classification will be used further.

**Tab. 5.2 Overview over the major process routes in the nickel winning from sulphidic ores. After (Hilbrans & Hinrichs (1999)).**

| Process              | Ore                       | Roasting              | Primary Smelting               | Matte converting | Separation co-product | Primary Refining    | Nickel Refining                        |
|----------------------|---------------------------|-----------------------|--------------------------------|------------------|-----------------------|---------------------|----------------------------------------|
| <b>alternative 1</b> | Nickel-concentrate        | fluidized bed furnace | Electric Furnace Smelting:     | Converter        |                       |                     | Matte refining (Electrorefining)       |
| <b>alternative 2</b> |                           |                       | Flash-Smelting                 | Converter        |                       |                     | Precipitation with hydrogen            |
| <b>alternative 3</b> | Nickel-Copper-Concentrate | fluidized bed furnace | Electric Furnace Smelting:     | Converter        | Wet                   | Roasting, reduction | Reductive electrolysis                 |
| <b>alternative 4</b> |                           |                       | Flash-Smelting                 | Converter        | Dry                   |                     | Electrolytic Refining (Electrowinning) |
| <b>alternative 5</b> |                           | Multiple hearth       | Reverberatory Furnace smelting | Converter        | Dry                   |                     | Carbonyl Process                       |

## 5.1.2 Emission

### Mining

The major emissions are due to mineral born pollutants in the effluents. The underground mining operations generate roughly 80 % of the dust emissions from open pit operations, since the major dust sources do not take place underground. Rain percolate through overburden and accounts to metal emissions to groundwater.

## Beneficiation

Ore handling and processing produce large amounts of dust, containing PM<sub>10</sub> and several metals from the ore itself. Flotation produce effluents containing several organic agents<sup>4</sup> used. Some of these chemicals evaporate and account for VOC emissions to air. Namely xanthates decompose hydrolytically to release carbon disulphide. Tailings effluent contains additional sulphuric acid from acid rock drainage.

## Metallurgy & Separation from Non Ferrous Metals

**Sulphur dioxide.** In all of the process steps sulphur dioxide is emitted to air. Recovery of sulphur dioxide is only economic for high concentrated off-gas. SO<sub>2</sub> emissions are by far the most important in the metallurgy.

**Carbon dioxide.** In the beneficiation step, considerable amounts of lime is added to the ore for pH-stabilisation, lime forms later flux in the metallurgical step. Lime decomposes into CO<sub>2</sub> to form calcite.

**Dust.** Dust carry over from the roasting, smelting and converting processes. Particulate emissions to the air consist of metals and thus are often returned to the leaching process after treatment.

**Chlorine.** Chlorine is used in some leaching stages and is produced during the subsequent electrolysis of chloride solution. The chlorine evolved is collected and re-used in the leach stage. The presence of chlorine in wastewater can lead to the formation of organic chlorine compounds (AOX) if solvents etc. are also present in a mixed wastewater.

**VOC.** VOCs can be emitted from the solvent extraction stages. A variety of solvents are used as they contain various complexing agents to form complexes with the desired metal that are soluble in the organic layer.

**Emissions to water.** Metals and their compounds and substances in suspension are the main pollutants emitted to water. The metals concerned are Cu, Ni, Co, As and Cr. Other significant substances are chlorides and sulphates. Wastewater from wet gas cleaning (if used) of the different metallurgical stages are the most important sources. The leaching stages are usually operated on a closed circuit and drainage systems, and are therefore regarded as minor sources.

## Refining

Also in this step the combustion of sulphur leads to emissions of SO<sub>2</sub>. Nitrogen oxides are produced in significant amounts during acid digestion using nitric acid. Chlorine and HCl can be formed during a number of digestion, electrolytic and purification processes. Chlorine is used extensively in the Miller process and in the dissolution stages using hydrochloric acid and chlorine mixtures respectively. Dust and metals are generally emitted from incinerators and furnaces. VOC can be emitted from solvent extraction processes, while organic compounds, namely dioxins, can be emitted from smelting stages resulting from the poor combustion of oil and plastic in the feed material. All these emissions are subject to abatement technologies and controlling. Large quantities of effluents contain amounts of metals and organic substances.

---

<sup>4</sup> Floating agents consist of collectors (xanthate or aerofloat) and frothing reagent (eg. Methyl Isobutyl Carbinol). Xanthates are a broad class of organic salts formed by treatment of an alcohol with carbon disulfide in the presence of an alkali, potassium ethyl xanthate (KC<sub>3</sub>H<sub>5</sub>S<sub>2</sub>O, CAS No: 140-89-6). Aerofloat is a salt of carbonyldithiophosphoric acids. A widely used frothing reagent is e.g. methyl isobutyl carbinol, CAS: 108-11-2, syn. Methyl Amyl Alcohol.

### 5.1.3 Waste

#### Mining and Beneficiation

Overburden is deposited close to the mine. Tailings are deposited as piles and in ponds. In both the overburden and the tailings, acid rock drainage occurs over a long period of time. These effects are handled in section IX “Non Ferrous Metal Winning – Auxiliary Processes”, chapter “Disposal of Tailings and Overburden”.

#### Metallurgy & Separation from Non Ferrous Metals

The production of metals is related to the generation of several co-products, residues and wastes, which are listed in the European Waste Catalogue. Some of the process specific residues can be reused or recovered in preliminary process steps (e. g. dross, filter dust) or construction (e. g. cleaned slag). Residues also arise from the treatment of liquid effluents, the main residue being gypsum waste and metal hydroxides from the wastewater neutralisation plant. These residuals have to be disposed, usually in lined ponds.

#### Refining

Like in the pyro- and hydrometallurgical step quantities of solid residuals are generated, which are mostly recycled within the process or sent to other specialists to recover any precious metals. Final residues generally comprise hydroxide filter cakes (ironhydroxide, 60% water, cat I industrial waste).

### 5.1.4 Class I Nickel in ecoinvent

In Hilbrans & Hinrichs (1999) data for the different process alternatives shown in Tab. 5.2 was collected in detail. However, in this study an average was calculated based on the values from alternative 1 to 5, weighted with their share to the world-wide production. The resulting module thus represents an aggregated value for the world-wide production of Class I nickel.

The module describes the global production mix for Class I nickel in 1994 with a coupled production of a certain amount of copper. The multioutput-process “nickel production, sulphidic ore, primary” delivers the co-products “nickel, 99.5%, at plant” and “copper, primary, coupleproduction nickel”. It is designed for the use of the metal as intermediate product or as raw material in the plating industry or the manufacturing of stainless steels and alloys. The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.3, Fig. 5.4, Fig. 5.5, Fig. 5.6, Fig. 5.7, Fig. 5.8 and Fig. 5.9. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one kilogram of Class I nickel.

#### Infrastructure and land use

The mobile equipment used for exploitation like drilling machines, scoop trams and underground trucks is inventoried with the diesel consumption stated in Hilbrans & Hinrichs (1999). The used module “diesel, burned in building machine” includes the infrastructure of the machines. 2000 m conveyor belts are further assumed with a capacity of 2000 t / h which gives 2E-5 m conveyor belt required per tonne mined raw ore. Since mining is underground and no heap leaching is done, no land use for exploitation is assumed.

Mining facilities and smeltery are inventoried with respective modules, beneficiation plant is approximated according to chapter II “Non Ferrous Metal Winning – Auxiliary Processes” with the module “aluminium hydroxide, plant”.

**Tab. 5.3 Infrastructure in underground mining, assumptions used. A lifetime of ten years are estimated, and 5000 working hours yearly.**

| action    | Machine        | throughput   | unit       | Infrastructure  |
|-----------|----------------|--------------|------------|-----------------|
|           |                | t / lifetime | Length (m) | m / t ore mined |
| Transport | Conveyor belts | 100'000'000  | 2000       | 2E-5            |

## Mining.

In the considered processes the ore is mined underground. The overburden is disposed in piles near the mine, the standard module for disposal of non-sulphidic overburden was chosen, which includes the land use and transformation through the disposal. Refilled overburden is assumed to be burden free, but cement and stowing material (assumption: sand) has to be added as stated in Hilbrans & Hinrichs (1999). The degree of the refilling is documented for each alternative in Hilbrans & Hinrichs (1999). Also water use and effluent from mining is documented. The use of freshwater was inventoried as river water, where as the pit water was assumed to be groundwater, which has to be pumped. The composition of the effluent was taken from IPPC (2002), its values are shown in Tab. 5.4. Concerning electricity mix Hilbrans & Hinrichs (1999) assumes a share of 60% of hydropower due to the operations high and constant energy demand. This assumption is used also in this inventory. Cement, explosives and sand are assumed to be transported by lorry over 50 km.

## Beneficiation

Once the ore is mined, it is ground and conditioned for further concentration. Considerable amounts of lime and flotation agents are added. The separated gangue is disposed in tailings ponds, the concentrated ore is fed to the metallurgy, which is assumed to be on-site.

Dust emissions comprise additionally the dust emissions due to mining activities. Like in the mining step, a share of 60% hydroelectricity was chosen according to Hilbrans & Hinrichs (1999).

**Lime.** Lime input was documented in Hilbrans & Hinrichs (1999) for each process alternative. The specific lime input ranges from 2.0 to 8.5 kg per t ore treated with a weighted mean of 5.5 kg / t ore.

**Reagents.** No information on mass and nature of the floating agents used are available. For copper mining a range of 25 – 300 g collector and 25 – 250 g frothing reagent per ton sulphidic ore is recommended (Krauss et al. (1999)). This is confirmed by the values in Tab. 5.5. Collector and frother are balanced in ecoinvent in their production as unspecified organic chemical. According to NPI (2001) xanthates hydrolytically decompose to 0.53 mg carbon disulphide per mg xanthate. With 189 mg xanthates from Tab. 5.5 this is 100 mg carbon disulphide per t mined ore (Tab. 5.6).

Activator and Depressants – excluding sodium cyanate – are modelled as unspecific inorganic chemicals, their emission to water is covered by reported emissions from mining sites shown in Tab. 5.4.

For pH adjustment and leaching the value for sulphuric acid was considered with 3.74 kg / t ore mined (Tab. 5.6). As sulphuric acid is a by-product from the metallurgy, it is regarded as burden free. Other acids are neglected.

Since composition and environmental fate of activator, depressant and sulphuric acid is uncertain, reported data for total emissions shown in Tab. 5.6 are taken. Note that some theoretical emissions due to the use of the reagents are higher than the reported ones in Tab. 5.4.

Sodium cyanide is widely used for extracting gold and other metals such as silver, copper and zinc. It is used as leachate and as depressant for certain sulphidic minerals. The environmental fate of cyanide compounds is complex and could not further be queried. A cyanide recovery of 80 – 90% is reported due to abatement and recovery in the Golden Cross mine in New Zealand (Anonymous (1998a)). Here a value of 80% is chosen for cyanide-abatement technology. With a reported use of 35 g NaCN per tonne ore mined (Tab. 5.5), this means a direct emission of 3.75 g CN<sup>-</sup> per tonne ore mined.

**Effluents.** Additional to direct emissions due to the use of chemicals, total emissions to water are chosen according to Tab. 5.4. These values are from base metal sites, thus only an approximation for the real effluent concentrations in the nickel production. It is assumed here that the effluents also include acid rock drainage (ARD). ARD after mine closure is modelled in the module “disposal, sulphidic tailings, off-site”.

**Dust.** A case study in Anonymous (1998b) about a projected open cut gold-copper mining and processing facility in Australia predict annual dust emissions between 0.18 kg/t and 0.46 kg/t of dust produced per tonne of ore mined. The prediction was made using the Emission Estimation Technique Manual for Mining (NPI (2001)). The maximum value of 0.46 kg/t is chosen for total dust emissions. Underground mining activities are assumed to generate 80 % of the dust emissions compared to open pit mining (Tab. 5.7) yielding a 0.37 kg dust per tonne mined ore. According to the IAEA<sup>5</sup> the dust composition is approximated with values of a specific sulphidic nickel ore in Tab. 5.8. For PM<sub>10</sub> values, the ratio TDS : PM<sub>10</sub> : PM<sub>2.5</sub> was approximated with values from copper ore mining 101.72 : 50 : 5 g / t ore taken from the CEMIP-database<sup>6</sup>, i. e. one tonne emitted dust corresponds to 491.5 kg PM<sub>10</sub> and 49.2 kg PM<sub>2.5</sub> respectively. The dust emissions resulting from underground activities are summed up in Tab. 5.8. In Ecoinvent, for particulates differential classes are used adding up to the total dust emission, i. e. 49.2 kg PM<2.5, 442 kg PM2.5-10 and 508 kg PM>10 per tonne dust

**Tab. 5.4 Mining & Beneficiation, emissions to water. Composition of effluents from mining activities, values are taken from total emissions to water from base metal sites in (IPPC (2002)).**

| Compound        | Unit                    | Range         | This study (geometric mean) | Number of Samples |
|-----------------|-------------------------|---------------|-----------------------------|-------------------|
| Discharge       | Mio. m <sup>3</sup> / a | 0.08 - 22.9   | 3.65                        | 6                 |
| Ca              | g / m <sup>3</sup>      | 686           | 686                         | 1                 |
| SO <sub>4</sub> | g / m <sup>3</sup>      | 1750 - 3175   | 2357                        | 2                 |
| COD             | g / m <sup>3</sup>      | 2.24 - 48.5   | 10.4                        | 2                 |
| Solids          | g / m <sup>3</sup>      | 2.38 - 11.3   | 5.17                        | 4                 |
| Al              | mg / m <sup>3</sup>     | 69.3 - 108    | 86.3                        | 2                 |
| As              | mg / m <sup>3</sup>     | 0.264 - 14.1  | 2.95                        | 3                 |
| Cd              | mg / m <sup>3</sup>     | 0.0901 - 1.02 | 0.316                       | 4                 |
| Co              | mg / m <sup>3</sup>     | 0.742 - 0.823 | 0.781                       | 2                 |
| Cr              | mg / m <sup>3</sup>     | 0.0311 - 9.62 | 0.547                       | 2                 |

| PM>10           | g / t ore  | 187.1                        |
| total dust      | g / t ore  | 368                          |

### Metallurgy and Separation of Copper as Co-product.

As shown in Tab. 5.2 there exist a variety of different production routes in the nickel metallurgy. In this study all five process alternatives were considered according to their production share given in Hilbrans & Hinrichs (1999). These alternatives cover at least 79 % of the world production of Class I nickel. The values thus already are aggregated and reflect the mix of the different alternatives within a certain process step, e. g. the electricity consumption in the roasting step. Consequently allocation factors for nickel differ from step to step.

**Drying** (alternative 2 &4). Flux is assumed to consist of 50% quartzsand and 50% lime, whose combustion releases 0.44 kg CO<sub>2</sub> per tonne lime, inventoried later in “overall process”. Drying is done by gas. According to Hilbrans & Hinrichs (1999), 40% of the electricity consumed is from grid, 60% is hydropower.

**Roasting** (alternative 1, 3 & 5). Flux is assumed to consist of 50% quartzsand and 50% lime, whose combustion releases 0.44 kg CO<sub>2</sub> per tonne lime, inventoried later in “overall process”. Drying is done by oil. According to Hilbrans & Hinrichs (1999), 40% of the electricity consumed is from grid, 60% is hydropower. A production of steam is reported in (Hilbrans & Hinrichs (1999)), which can not be accounted for as benefit.

**Smelting** (all alternatives). Smelting is mainly done by oil (alternative 5, fluidized bed kiln) and in alternative 4 high amounts of coke are required. 40% electricity are from grid, 60% hydropower assumed. A production of steam is reported, which can not be accounted for as benefit. Dust emissions from smelting are inventoried later under “overall process”. Here the major part of the sulphur dioxide is emitted. The value of 1,5 t SO<sub>2</sub> per tonne metal produced includes also the sulphur dioxide emissions from drying and roasting. This value is reported at INCO’s environmental report for the sud-

<sup>7</sup> [http://www.air.sk/tno/cepmeip/em\\_factors.php](http://www.air.sk/tno/cepmeip/em_factors.php), accessed 01.03.2003

bury's operation<sup>8</sup>. It was chosen because it probably depicts the global situation more accurate than the much lower values reported in (IPPC (2001)) reflecting the European situation with 0.164 t SO<sub>2</sub> / t, or the much higher value from the Russian operation at Noril'sk (5.3 t SO<sub>2</sub>/ t) reported in (Hochfeld (1997)).

**Converting** (all alternatives). Converting is done by gas. According to Hilbrans & Hinrichs (1999), 40% of the electricity consumed is from grid, 60% is hydropower. A production of steam is reported in (Hilbrans & Hinrichs (1999)), which can not be accounted for as benefit. Reported dust emissions are not fugitive, they are caught in the wet scrubber and form a residue, which has to be disposed. Fugitive dust emissions are inventoried later under "overall process".

**Sulphuric acid production** (all alternatives). For production 40% electricity from grid, 60% hydropower assumed. The acid formed is not inventoried because it is assumed to be a by-product.

**Other processes** (all alternatives). Different electricity use from facilities etc. 40% of the electricity from grid, 60% hydropower assumed.

**Leaching / copper separation** (alternatives 3, 4 & 5). Pyrometallurgical separation is done by gas. 40% electricity from grid, 60% hydropower assumed. Leaching agents reported in (Hilbrans & Hinrichs (1999)) are approximated with the inventory for ammoniac production but no process emissions were considered due to lack of data. Ammonium sulphate as by-product from alternative 2 was not inventoried and assumed to be burden free (cut off).

**Overall process.** The emissions to air are taken from different sources as shown in Tab. 5.9. Effluents were approximated with the value of 1.4 m<sup>3</sup> per tonne concentrate worked from PGM-operations reported in (Hochfeld (1997)) (Tab. 5.10). The emissions due to the effluent are taken from (IPPC (2001)). Carbon dioxide from the calcination of lime added in several steps before is released at a rate of 0.44 t CO<sub>2</sub> per tonne lime added.

**Purification.** Until this step all inventory was allocated according the revenue obtained by co-production of copper in alternatives 3, 4 & 5 (The only exception is the resource that is allocated by mass (34% to copper)). In this purification step the inventory is fully allocated to nickel since no copper is present any more. Each alternative differs from each other. An overview over the different contributions is given in Fig. 5.7. No data on chlorine input and related emissions is available. For the reduction with hydrogen (alternative 2) a simple stoichiometry Ni:H of 59:1 yielding and a reaction efficiency of 90% was assumed, yielding a necessary input of 19.1 kg hydrogen per tonne nickel reduced. For all electricity use a share of 40% electricity from grid and 60% hydropower was assumed.

<sup>8</sup> globally operating nickel producer, <http://www.inco.com>

**Tab. 5.9 Emissions to air per tonne produced metal.** Data was taken from similar processes in nickel (A) and copper (B) metallurgy and multiplied with the sum of produced metals (PGM, Ni & Cu). Data is taken from (IPPC (2001)), the distribution of the particle size is taken from CEPMEIP<sup>9</sup> (C). VOC emission from leaching (D). In this study values for SO<sub>2</sub> emissions are estimated roughly with 1.5 t / t Ni as stated in the environmental report of the sudbury operation.

**Tab. 5.10 Composition of different wastewater effluents after treatment.** A simple average from different reported values of European copper operations is chosen (IPPC (2001)). Values in the columns “process water”, “surface run off” and “direct cooling water” represent geometric means of the range reported. Values for Cr, Hg and Sn correspond to a copper semis production site, reported in (IPPC (2001)).

**Data quality**

**Mining.** Data for major mass fluxes are satisfactory, while the emissions in to water may be overestimated due to different system boundaries of reported effluent volume from Hilbrans & Hinrichs (1999) and total effluent emissions reported in IPPC (2002).

**Beneficiation.** Like in mining, the emissions to water can be overestimated. The emissions from tailings are assessed in an extern module, which itself contains rough assumptions of a global overburden and tailings composition and a simplified disposal scenario. Emissions though can vary considerably from case to case.

**Metallurgy.** Process data is satisfactory and valid for over 90 % of the Class I nickel production. The main emissions dominating possibly the whole process is sulphur dioxide, which is not reported in Hilbrans & Hinrichs (1999). The chosen value of a single operation is consistent with other reported values in IPPC (2001) and Hochfeld (1997). Poor data are available on composition and fate of solid waste, the reuse rate was documented.

**Separation of copper and further refining.** Main data on energy and mass fluxes is satisfactory, while data on direct emissions due to hydrometallurgical processes is poor. Namely chlorine emissions can be considerable, generating both HCl emissions to air and AOX emissions to water – emissions which are not assessed in this work. An other emission, which is not inventoried due to poor data, is carbondisulfide used in alternative 5 in considerable amounts.

Fig. 5.5 Flows for the multi-output process “Nickel production” (part drying/roasting) and its representation in the ecoinvent database. Values correspond to the functional unit of 1 kg Class I nickel. Allocation values indicate the amount of the flow that is allocated to the co-product copper.

Fig. 5.6 Flows for the multi-output process “Nickel production” (part smelting/converting) and its representation in the ecoinvent database. Values correspond to the functional unit of 1 kg Class I nickel. Allocation values indicate the amount of the flow that is allocated to the co-product copper.

Fig. 5.7 Flows for the multi-output process “Nickel production” (part sulphuric acid / copper separation) and its representation in the ecoinvent database. Values correspond to the functional unit of 1 kg Class I nickel. Allocation values indicate the amount of the flow that is allocated to the co-product copper.

## 5.2 Ferronickel

This part is mainly based on Hilbrans & Hinrichs (1999). General process description was taken from Kerfoot (1997).

### 5.2.1 Production process and infrastructure

**Mining.** Nickel oxide ores occur in two types: a limonitic type which occurs in the upper zone of a lateritic deposit, in which ferric oxide materials are predominant, and a silicate, occurring at greater depth in the deposit, which has lower iron content, but is usually richer in nickel than the limonite, and contains high levels of magnesia and silica. Most deposits contain both types of ore. Usually it is possible to separate the ore by selective mining and screening into an iron-containing limonite fraction and a magnesium silicate fraction enriched in nickel.

**Beneficiation.** Two processes – the Nippon Yakin Oheyama and the MINPRO–PAMCO process – have been developed in which the nickel is first converted by high-temperature treatment to a metallic phase, which can then be separated from the bulk of the ore by standard mineral beneficiation techniques.

**Metallurgy.** The metallurgy of nickel oxide ores differs from that of sulphides in that oxide ores are not amenable to most of the standard mineral beneficiation methods due to the chemical dissemination of the nickel in the oxide minerals. Nickel laterite ores have high moisture contents (typically up to 45 %) as well as chemically bound water in the hydroxide form. For this, the ore has to be dried, usually direct-fired rotary units operating at about 250 °C, to 15 – 20 % moisture. Calcining to dehydrate the ore and prereduction prior to electric furnace smelting are generally carried out. Chemically bound water is released above ca. 400 °C, reduction of the oxides to metal starts at 500 – 600 °C. Dehydration and pre-reduction of the ore in the kiln prior to smelting, optimises the utilisation of energy available from the reductants and fuel, thus reducing energy consumption in the smelting operation.

Class II nickel products such as nickel oxide, metallised nickel oxide, and ferronickel, are produced directly by smelting and roasting. They are sufficiently pure without refining for many nickel applications such as stainless steel production. The rotary kiln – electric furnace smelting process is now used almost universally for the production of ferronickel from oxide ores. Also ores with a low Ni/Fe ratio can be smelted to yield an acceptable ferronickel grade.

**Ferronickel refining.** Crude ferronickel produced by the conventional rotary kiln – electric furnace process usually contains high levels of carbon and sulphur. These ferronickels are first treated under reducing conditions to remove sulphur and are then refined sequentially under oxidising conditions with suitable fluxes to remove carbon, silicon, and phosphorus. A variety of equipment is used for the refining of ferronickel, including electric arc furnaces, shaking ladles, and low-frequency induction furnaces for desulphurisation, and oxygen-blown converters for silicon, carbon, and phosphorus removal. Sulphur is generally removed under reducing conditions by adding soda ash, lime, or calcium carbide to the molten ferronickel. Good agitation of the melt is essential to ensure effective mixing of the reagent with the metal phase

### 5.2.2 Emission

#### Mining

The major emissions are due to mineral born pollutants in the effluents. Mining operations generate large amounts of dust. Rain percolate through overburden and accounts to metal emissions to groundwater.

## Beneficiation

Beneficiation is done by classification, no emissions arise from this step.

### Metallurgy & Separation from Non Ferrous Metals

**Carbon dioxide.** In the ore pre-treatment, considerable amounts of lime are added. Lime decomposes into CO<sub>2</sub> to form calcite.

**Dust.** Dust carry over from the roasting, smelting and converting processes. Particulate emissions to the air consist of metals and thus are often returned to the leaching process after treatment. Dust consists to a considerable part of heavy metals.

**Other emissions to air.** The most important pollutants from the production of ferro-alloys in general besides dust are SO<sub>2</sub>, NO<sub>x</sub>, CO, CO<sub>2</sub>, HF, PAH and VOC. Only few SO<sub>2</sub> coming from metallurgical coke is formed.

**Emissions to water.** Metals and their compounds and substances in suspension are the main pollutants emitted to water. The metals concerned are Zn, Fe, Co, Pb and Hg. Other significant substances are chlorides and sulphates. Wastewaters from wet gas cleaning (if used) of the different metallurgical stages are the most important sources. The leaching stages are usually operated on closed circuit and drainage systems, and are therefore regarded as minor sources.

## 5.2.3 Waste

### Mining and Beneficiation

Overburden is deposited close inside the mine panel. Since no further beneficiation takes place in the ferronickel production, no beneficiation tailings arise.

### Metallurgy & Separation from Non Ferrous Metals

The production of metals is related to the generation of several residues and wastes, which are listed in the European Waste Catalogue. The most specific residues are filter dusts, sludge from wet scrubbers, slag from the smelting process, used furnace linings and packaging material like drums or big-bags. These residues are partly sold as by-products, recycled to the process or in cases of wastes without economic utility transported to a deposit or a landfill.

Some of the process specific residues can be reused or recovered in preliminary process steps (e. g. dross, filter dust) or construction (e. g. cleaned slag). Residues also arise from the treatment of liquid effluents, the main residue being gypsum waste and metal hydroxides from the wastewater neutralisation plant. These residuals have to be disposed, usually in lined ponds.

## 5.2.4 Ferronickel in ecoinvent

The module describes the global ferronickel production in 1994. It is designed for the use of the alloy as raw material in the manufacturing of stainless steels and alloys. The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.10, Fig. 5.11 and Fig. 5.12. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one kg of ferronickel. A general description of the module and a summary of its meta information can be found in Tab. 5.1.

### Infrastructure and land use

The mobile equipment used for exploitation like drilling machines, scoop trams and underground trucks is inventoried with the diesel consumption stated in Hilbrans & Hinrichs (1999). The used module “diesel, burned in building machine” includes the infrastructure of the machines. 10'000m conveyor belts are further assumed with a capacity of 2000 t / h which yields 2E-5 m conveyor belt required per tonne mined raw ore.

Transformation and occupation of land through direct exploitation are assumed with the standard value for non-ferrous metals without heap leaching processes of 0.0025 m<sup>2</sup>/t and 0.075 m<sup>2</sup>/t ore mined, that is 0.055 m<sup>2</sup>/t and 1.65 m<sup>2</sup>/t per tonne Nickel produced.

Mining facilities and smeltery are inventoried with respective modules according to chapter II “Non Ferrous Metal Winning – Auxiliary Processes”.

### **Mining.**

In the considered processes the ore is mined in open cuts. The overburden is disposed in piles inside the mining panel, therefore no disposal of overburden is assumed (Hilbrans & Hinrichs (1999)). Also water use and effluent from mining is documented in Hilbrans & Hinrichs (1999). The use of freshwater was inventoried as river water, where as the pit water was assumed to be groundwater, which has to be pumped. The composition of the effluent was taken from IPPC (2002), its values are shown in Tab. 5.4. Concerning electricity mix Hilbrans & Hinrichs (1999) assumes a share of 60% of hydropower due to the operations high and constant energy demand. This assumption is used also in this inventory. For laterites no further beneficiation is necessary and possible except classification. Therefore no tailings arise.

### **Metallurgy**

**Energy.** In Hilbrans & Hinrichs (1999) the energy demand for drying and roasting of the wet ore is stated, which contributes to a major extent to the overall energy demand in the ferronickel production (Fig. 5.11).

**Flux.** The input of limestone is estimated roughly with values reported from the related manufacturing processes for ferro-chrome and calcium silicate in IPPC (2001). Choosing a geometric mean of the values a value of 470 kg limestone per tonne ferro-alloy is required. Consequentially 0.44 kg CO<sub>2</sub> per tonne flux is emitted after the formula  $\text{CaCO}_3 \rightarrow \text{CaO} + \text{CO}_2$ .

**Dust.** The emission of dust is estimated roughly considering values from ferro-chrome production. There overall values ranging from 0.5 to 1 kg per tonne ferro-alloy is reported in IPPC (2001). In this study a value of 1 kg per tonne is chosen using a PM-partition reported in CEPMEIP<sup>10</sup>. Dust composition is approximated with the specific values from class I nickel production in this section, resulting in emission factors in Tab. 5.11.

**Effluent.** Specific value of 6.9 m<sup>3</sup> per tonne ferro-alloy chosen from IPPC (2001).

**Air emissions.** No VOC-emissions were assumed since no hydrometallurgical processes are considered. For TCDD the same values as in class I nickel metallurgy are chosen (IPPC (2001)).

### **Data quality**

**Mining.** Data for major mass fluxes are satisfactory, while the emissions in to water may be overestimated due to different system boundaries of reported effluent volume from Hilbrans & Hinrichs (1999) and total effluent emissions reported in IPPC (2002).

**Metallurgy.** Process data is satisfactory. Poor data are available on composition and fate of solid waste, which has to be seen as major impact within the overall process due to its big mass.

EMPA Dübendorf, Swiss Centre for Life Cycle Inventories, Dübendorf, CH, Online-Version under: [www.ecoinvent.ch](http://www.ecoinvent.ch).

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1.

## Comments on version 2.1

This part corresponds to the original report in Althaus et al. (2004) that has been updated with the changes reported in Frischknecht et al. (2006). The changes were implemented with v1.3 affect the co-product dataset of nickel due to an incorrect nickel price underlying the allocation factors.

The correction caused an increase of attributed exchanges for nickel and a decrease for the others, especially in the case of PGM-production in Russia, since there the co-product nickel has a considerable share in the output.

No changes were made in version 2.1 compared to version 2.0.

Chapter “6 Cumulative Results and Interpretation” of the original report has been deleted for the current update. Note that the flow names in the tables displaying unit processes have not been updated to reflect the name changes with version 2.0. This namely affects the designation of transportation service flows.

## Summary

The primary production of platinum group metals (PGM) is modelled for South Africa and Russia. Together these two countries produce more than 90% of the world’s PGM.

For the secondary production of PGM the recycling process of automotive catalysts is modelled.

The consumer mixes for PGM in Europe are finally modelled from the outputs of these three modules.

Mining, beneficiation and the different metallurgical processes are inventoried vertically aggregated because of difficulties to clearly allocate some of the flows to one single step and because the intermediate steps would not make sense in another context. The Figures in this report however contain the available information to the single steps.

# 1 Introduction

This chapter describes the production of the platinum-group metals Platinum (Pt); Palladium (Pd) and Rhodium (Rh) from cradle to consumer in Europe. Inventory data is taken mainly from (Hochfeld (1997)) with background data from (IPPC (2002)) and (IPPC (2001)). Market data on PGM and non ferrous metals are provided by Johnson Matthey<sup>1</sup> and the London Metal Exchange respectively<sup>2</sup>.

Since the PGM are associated with other metals, their production always yields a fraction of other metals than PGM, mainly Nickel (Ni) and Copper (Cu). Hence the process of primary production described in this chapter is formally a multioutput-process with the coupled products Pt, Pd, Rh, Ni and Cu. This makes it necessary to allocate the inventory to these products. The demand of PGM-containing ore is allocated by mass. The rest of the inventory is allocated by revenue.

PGM are highly valuable, their occurrence is scarce. PGM-containing ores are mined only in few sites. The deposits in Noril'sk (RUS) and Bushveld (RSA) contribute over 90% to the global PGM-production. The data on these two PGM winning operations therefore represents the global primary production of PGM according to their market share.

The great value of the PGM makes recycling profitable to some extent. This secondary production is approximated with the declared amount of metal from the recycling of automotive catalysts. For Europe this assumption is reasonable, since automotive catalysts account for over 90% of the metal use.

The market for PGM is of great importance. On the one hand, market prices determine the profitability of the PGM winning, both for primary and secondary production. On the other hand the inventory is allocated by revenue to the different metals. An ecological assessment of PGM therefore is always dependent on the actual market situation. Further more, the producing countries hold stocks of PGM in order to influence market price and to protect their own PGM-demanding industries. As precious metal, Platinum in particular is dealt as investment.

## 2 Reserves and Resources of PGM

Metals are a special class of materials. They are not consumed but rather used during a product life cycle. When recovered the properties are theoretically identical. The metal can be re-used in another product life cycle, provided that its concentration makes a recovery profitable. The recovered metal is referred to as secondary metal, whereas the metal originating directly from the ore is referred to as primary metal. In LCIs these two types – primary and secondary metal – are often differentiated because they bear a different ecological burden.

### 2.1 Primary PGM

The PGMs in primary deposits have been transferred from the earth's interior. Tectonic movements of the earth's crust, followed by the eruption of magma, have led to their presence in regions close to the surface. Almost invariably, the platinum group elements have separated from ultrabasic magmas. Norite (Mg – Fe – Ca – Al silicate) contains mainly sulphidic intrusions, whereas intrusions in dunite (Mg – Fe silicate) are mainly sulphide free.

When primary deposits are washed and weathered, secondary deposits are formed, also known as placers or alluvial deposits. Mechanical concentration of the heavy constituents by flowing water takes place, together with chemical dissolution and precipitation of the platinum group metals. Alluvial deposits usually originate from dunite. For easily washable sand, a PGM content of 0.05 ppm is economic.

The PGMs occur in a large number of minerals. Workable ore deposits contain mainly sperrylite (PtAs<sub>2</sub>), cooperite (PtS), stibiopalladinite (Pd<sub>3</sub>Sb), laurite (RuS<sub>2</sub>), ferroplatinum (Fe – Pt), polyxene (Fe – Pt – other platinum metals), osmiridium (Os – Ir), and iridium platinum (Ir – Pt). These minerals are associated with particular carrier materials, e.g., iron pyrites, nickel iron pyrites, or chrome iron ore (Renner (1997)).

The ratio and concentration of the PGM and their accompanying metals vary from site to site (s. Tab. 2.1). PGM deposits can be classified into the types oxidic-silicatic associations (e. g. UG2) and sulphidic associations, which can further be divided into PGM-dominated (e. g. Merensky, Stillwater) and Ni-Cu-dominated (Sudbury, Norsil'sk) (Hochfeld (1997)). Of the estimated 112'900 t PGM-resources 55.6% are supposed to be found in South Africa, 15.9% in Russia, 12.3% in Finland, 8.9% in Zimbabwe and 6.0% in the USA (Hochfeld (1997)). However, the PGM-reserves – the profitable workable deposits – are mainly located in South Africa and Russia (s. Fig. 2.1).

**Tab. 2.1 Characteristic metal concentrations in the most important PGM-mining sites. Data from Hochfeld (1997)**

| Element |     | Merensky          | UG2               | Stillwater        | Sudbury           | Noril'sk           |

| Rh      | ppm | 0.24              | 0.54              | 0.21              | 0.03              | 0.2                |
| Ru      | ppm | 0.44 <sup>2</sup> | 0.72 <sup>2</sup> | 0.36 <sup>2</sup> | 0.04 <sup>2</sup> | n. a. <sup>2</sup> |
| Ir      | ppm | 0.06 <sup>2</sup> | 0.11 <sup>2</sup> | 0.21 <sup>2</sup> | 0.01 <sup>2</sup> | n. a. <sup>2</sup> |
| Os      | ppm | 0.04 <sup>2</sup> | 0.07 <sup>2</sup> | - <sup>2</sup>    | 0.01 <sup>2</sup> | n. a. <sup>2</sup> |
| Au      | ppm | 0.26              | 0.07              | 0.21              | -                 | 0.25 <sup>2</sup>  |

<sup>2</sup> Values for Ru, Ir and Os are taken from Hagelücken (2001b).

**Fig. 2.1 PGM-reserves by region.** Reserves are defined as at the present time profitably workable deposits. The global PGM-resources are estimated to be 112'900 t. "Multiple of annual demand" indicates the years until the actual resources are depleted assuming a constant demand.

Today worked ores are from primary deposits, whereas earlier mainly placers in Russia (Ural) were exploited. Production mainly depends on the market price of the PGMs and the accompanying metals like Ni or Cu. As seen from geographical distribution of the main resources, major producers are located in South Africa (RSA) on the Bushveld Complex (Merensky-Reef and UG2) and in the Russian Federation (RUS) at Noril'sk-Talnakh. These two major sites account for over 90 % of the PGM production world-wide. The deposits in RSA are mined by seven big companies in RUS the company Norilsk Nickel is responsible for the whole exploitation. Fig. 2.2, Fig. 2.3 and Fig. 2.4 show the development of the production of platinum, palladium and rhodium respectively split by country. Other PGM winning countries are the USA (Stillwater), Canada (Sudbury) and Zimbabwe. They contribute only little to the global supply even though the capacity of the US palladium deposit has been greatly increased in recent years.

**Fig. 2.2** Platinum production by country. Bold line represents total supply in tonnes. Grey areas indicate the countries share in the global supply. Data taken from JohnsonMatthey (2003), grey areas correspond to the axis on the left (percentage of total supply), whereas the total supply correspond to the axis on the right (supply in tonnes).

**Fig. 2.3** Palladium production by country. Bold line represents total supply in tonnes. Grey areas indicate the countries share in the global supply. Data taken from (JohnsonMatthey (2003)), grey areas correspond to the axis on the left (percentage of total supply), whereas the total supply correspond to the axis on the right (supply in tonnes).

**Fig. 2.4** Rhodium production by country. Bold line represents total supply in tonnes. Grey areas indicate the countries share in the global supply. Data taken from JohnsonMatthey (2003), grey areas correspond to the axis on the left (percentage of total supply), whereas the total supply correspond to the axis on the right (supply in tonnes).

## 2.2 Secondary PGM

Another important source is the recovery of secondary PGM metals. Large amounts of PGMs are used in automotive catalysts. Due to the high value of the metals, automotive catalysts are recovered. They are dismantled, the ceramic carrier then is dissolved and the metals regained through hydrometallurgical processes. This source is still small compared to the total demand world-wide, but it is rising. In the USA already 11.5 t of total 40.1 t platinum used in 2001 originated from automotive catalysts. This value is higher than in Europe because of the earlier introduction of automotive catalysts. The pool of PGM in US automotive catalysts is stable. In Europe and Japan this pool still rises until steady-state is reached with a recovery of expected 52% of all used automotive catalysts for Germany (Hagelücken (2001b)). This future recovery quota is uncertain, because the PGM recovery depends mainly on the market price. Further development probably will lead to a higher demand and thus to a higher recovery quota. The actual recovery in Europe amounts 2.8 t, 1.4t and 1.1t for platinum, palladium and rhodium respectively (for calculations and comments see. 5.1.2 Secondary Production).

Large quantities of secondary materials are present in the form of used Pt-Rh gauze, used for catalytic formation of nitric acid. At the present, the pool of such gauze amounts about 50 t world-wide. Also the glass industry generates large quantities of defective components for recovery. Defective laboratory equipment – crucibles and dishes – makes a considerable contribution. Also large quantities of Pt- and Rh-containing thermocouple components are provided by the electrical industry (Renner (1997)). In addition, an increasing proportion of the cars currently being scrapped are fitted with catalysts – it was only in 1993 that all new gasoline cars in Europe were equipped with catalytic converters. This will lead consequently to a higher amount of PGM's recovered.

Often, the recovery operation is included in the sales contract. Materials are sent directly for recovery and do not appear on the raw materials market. Because of this, no data on the recovery of the existing PGM pool is available.

## 3 Characterisation of the PGMs

This chapter is mainly based on information provided by the International Platinum Association's website<sup>3</sup>. Some physical and chemical properties of the PGMs are summed up in Tab. 3.1.

### 3.1 Platinum

Platinum is a silvery-white metal and is probably best known for its use in jewellery. However, jewellery actually represents only about 38% of overall platinum use, an equivalent volume of platinum is used in catalytic converters, with the remaining 20% being used in other industrial applications.

Platinum is hard and extremely dense. Platinum and its relatives, iridium and osmium, are the most dense metals known (platinum is nearly twice as dense as lead and 11% more dense than gold). It has a high melting point and high temperature stability and corrosion resistance; and it is a good oxidation catalyst, conductive and oxidation resistant. It's biological compatibility makes it an important component in medical applications.

### 3.2 Palladium

Like platinum, palladium is silvery-white in colour. Its melting point is the lowest of all PMG, but it is still high compared to other popular metals. It is also the least dense of the PMGs. It has also high temperature stability and corrosion resistance. The rarest of all PGMs apart from iridium, palladium is also a good oxidation catalyst, conductive, oxidation resistant and ductile when annealed.

Palladium has the ability to absorb big amounts of hydrogen. This makes it an efficient and safe hydrogen storage medium and purifier. It is also used in chemical processes that require hydrogen exchange between two reactants, such as that which produces butadiene and cyclohexane, the raw materials for synthetic rubber and nylon.

Palladium's catalytic qualities make it necessary in catalytic converters and air purification equipment. Its chemical stability and electrical conductivity lead to more effective and durable plating than using gold in electronic components.

### 3.3 Rhodium

Its hardness makes it an alloying agent to harden platinum. With this hardness, along with its high melting point, high temperature stability and corrosion resistance, rhodium is used in many industrial processes such as glass, glass fibre and nitric acid production. Like other PGMs, Rhodium has catalytic qualities, and thus is used in catalytic converters.

## 4 Use / Application of PGM

Common to all of the PGMs is their use in electronics and as an element in catalytic converters. Catalytic converters are mainly used in automobiles, in the petroleum industry and hydrogen fuel cells. The use in automotive catalysts covers a good part of the overall PGM demand, in the case of Rhodium it amounts over 80%. The resource needed for automotive catalysts is covered partly from recycled automotive catalysts. This share differs greatly from country to country.

Second largest segment is the use of the metals in jewellery, namely in the case of Platinum. Another important field of application is the use in dental alloys.

Magnetic alloys containing platinum (mainly with cobalt) are components in the hard disks of 90% of the computers manufactured 2001. It is the largest single electronic application for platinum with rapidly increasing demand.

PGM catalysts for nitric acid production take the form of gauze made out of fine wire. Rhodium is added for strength and to reduce the amount of platinum loss during the conversion of the gas.

PGMs are widely used in medicine because they are inert and do not corrode inside the body. Allergic reactions to PGM are extremely rare. They have good electrical conductivity, which makes them an ideal electrode material.

Tab. 4.1 resumes the use of different PGMs, Fig. 4.1, Fig. 4.2 and Fig. 4.3 show the PGM demand by application in 2001.

The demand of the different PGM varies greatly depending on stocks and price. Overall, the platinum used equals in magnitude the demand of palladium (198 t Pt or 6'370 troz<sup>4</sup> and 4'880 troz or 152 t Pd respectively in 2002), whereas the demand of Rhodium of 18 t or 568 troz is markedly smaller (JohnsonMatthey (2003)).

**Tab. 4.1 Main applications of PGMs. Table taken from Johnson Matthey<sup>5</sup>**

| Application         |                                   | PGMs used      |
|---------------------|-----------------------------------|----------------|
| Automotive catalyst | control of vehicle pollution      | Pt, Pd, Rh     |
| Chemical            | catalysts for chemical synthesis  | Pt, Pd, Rh, Ru |
|                     | electrode coating                 | Ir, Ru         |
| Dental              | alloys for dental restorations    | Pt, Pd         |
| Electronics         | computer hard disks               | Pt             |
|                     | multi-layer ceramic capacitors    | Pd             |
|                     | crucibles to grow single crystals | Ir             |
| Fuel Cells          | catalysts for power generation    | Pt             |
| Glass               | glassmaking equipment             | Pt, Rh         |
| Investment          | coins and bars                    | Pt             |
| Jewellery           | wedding rings, fashion jewellery  | Pt             |
| Medical             | anti-cancer drugs, implants       | Pt             |
| Petroleum           | catalysts for gasoline refining   | Pt             |
| Sensors             | temperature & gas sensing         | Pt, Rh         |
| Other               | spark plugs, pollution control    | Pt, Ir         |

<sup>4</sup> troz = troy ounce, 1'000 troz correspond to 31.1 kg.

## 5 System Characterisation

Platinum group metal, which is consumed in Europe, consists of a certain fraction of secondary materials originating from scrap. This fraction of secondary material is joined before consumption with primary material, originating from ore. Two single plants are responsible for around 90% of the primary platinum, palladium and rhodium production – these are the operations in Norsil'sk in Russia and in the Bushveld Complex in South Africa. The PGM are however not the only noteworthy products of these enterprises. Namely Noril'sk Nikkel production is characterised by the production of nickel and copper, PGM being a co-product. This fact makes it obvious that the ecological burden arising from the primary production has to be allocated to the primary products nickel, copper, platinum, palladium and rhodium. The same is true for the secondary production, where the metal values are recovered jointly. Fig. 5.1 gives an overview over the process scheme and the corresponding modules in ecoinvent.

Fig. 5.1 Scheme of the PGM production in ecoinvent.

## 5.1 Allocation

The PGM production in ecoinvent is described formally as multi output process, yielding the coupled products nickel, copper and PGM as a mixture. The next chapter explains the allocation procedure in detail.

### 5.1.1 Primary Production

The exact ratio of the different PGMs present in this mixture is not reported in the literature used. It was assumed that the ratio of the PGM produced corresponds to the corresponding ratio in the raw ore (see Tab. 2.1).

For the coupled production of Ni, Cu and PGM the demand of ore is allocated according to the production output by mass Hochfeld (1997). The ore is handled in ecoinvent as a mixed ore with 4.7E-4% Pt, 3.1E-4% Pd, 0.2E-4% Rh in crude ore. The copper and nickel content in the ore depends on the deposit. For RU it is 3.2% and 2.3% respectively and for ZA the copper content is 0.052% and the

nickel content is 0.037%. As copper and nickel are leaving the PGM production before the final refining step, the burdens of refining are allocated only to PGM while the burdens of the other steps are allocated to copper, nickel and the PGMs. Thus different overall allocation factors for the different inventory flows are established depending on the flows occurrence and magnitude in the different production steps.

For all inventories other than ore an allocation by revenue is made, because this reflects economic reality of metal mining in a higher degree than an allocation by mass. Exploitation of an ore is always dependent on sufficient revenue expected. If a specific ore lacks sufficient revenue expected, it is not mined. Already mined ore with insufficient metal content usually is put aside for further beneficiation at a later time, at which market prices allow a profitable production of the metal. As ores contain different metals, the overall accounting of all metals produced is decisive. Even if the winning of a certain single metal is not profitable, it may be through cross-subsidising by another more profitable co-product. Thus the standard way chosen to allocate ecological burdens – except the demand of ore – is the allocation by revenue.

As PGM-mining companies have long term decision horizons, the average price of the last ten year period was chosen, this is for Pt, Pd and Rh US\$ 14'000, US\$ 9'420 and US\$ 30'700 per kilogram respectively<sup>7</sup>. The prices for Ni and Cu in this time period were US\$ 6.65 and US\$ 1.99 per kilogram respectively<sup>8</sup>. The fluctuation in price is documented in Fig. 5.2, Fig. 5.3, Fig. 5.4 and Fig. 5.5. Allocation and environmental burden may change depending on the period the price average is based on.

Tab. 5.1 gives a summary of the values chosen to calculate the allocation factors in the primary production. The resulting factors are summed up in Tab. 5.2

### 5.1.2 Secondary Production

Similar considerations are made for the allocation of secondary PGMs that originate from recovered automotive catalysts. It is assumed that all the secondary metal comes from automotive catalysts. Other sources of scrap were neglected. As in primary production, no data on the ratio of single PGM produced was available. This ratio differs greatly from scrap to scrap. Instead of the ore composition like in primary production, here the amount of annually recovered Pt, Pd and Rh respectively (in Europe) are chosen as proxy for the scrap composition. This composition ratio was used for allocation by mass. Multiplication with the market price gives the ratio used for the allocation by revenue.

Since no data on European rhodium recovery was available, it was approximated with the figure for global recovery rate of 15%<sup>9</sup> and a total annual Rh demand in Europe of 6.4 t. For the year 2002 this gives an amount of 1.11 t/a recovered Rh in Europe. The figures for Pt and Pd recovered in Europe are documented and amount 2.80 t/a Pt and 1.40 t/a Pd in the year 2002 (JohnsonMatthey (2003)).

This ratio of 1.11t/a : 1.40t/a : 2.80t/a for Rhodium : Palladium : Platinum corresponds to allocation factors summed up in Tab. 5.2.

<sup>7</sup> Data taken from Johnson Matthey's Website "Platinum Today", <http://www.platinum.matthey.com>, accessed at 01.03.2003

<sup>8</sup> Data taken from "London Metal Exchange", [http://www.lme.co.uk/data\\_prices/home.html](http://www.lme.co.uk/data_prices/home.html), accessed at 01.03.2003

<sup>9</sup> Total global rhodium demand of 20.7 t and an amount of 3.08 t recovered from automotive catalysts world-wide gives secondary rhodium a share of 15 % in the global demand.

**Tab. 5.2** Resulting factors for allocation based on values shown in Tab. 5.1. These factors allocate the ecological burden to the respective products. Allocation by mass reflects the PGM composition in the raw material (ore, scrap). Allocation by revenue is calculated by multiplication of the PGM content in the raw material with the respective market price. The allocation by mass is solely used for the allocation of PGM-ore to the respective products.

| Products  | Primary Production      |                         |                            |                            | Secondary Production      |                              |

## 5.2 PGM consumer mix

In ecoinvent, following modules represent the use of platinum, palladium and rhodium in Europe (consumer mix):

- “platinum, at regional storage ”
- “palladium, at regional storage ”
- “rhodium, at regional storage ”

The consumer mix is an assembly of the primary PGM transported from ZA and RU to Europe and secondary PGM, which are recovered and consumed in Europe (Fig. 5.6). The modules for primary and secondary production are described in the sections 5.3 and 5.4 respectively.

The layout of the modules with general flow information, remarks and values are shown in Fig. 5.7, Fig. 5.8 and Fig. 5.9. An overview over the module’s general information and metadata is given in Tab. 5.3

**Fig. 5.6** Scheme of the PGM, at regional storage, in ecoinvent.

**Tab. 5.3 Ecoinvent meta information for the modules of consumption of platinum, palladium and rhodium.**

| <b>Name</b>                  | <b>palladium, at regional storage</b>                                                                                                                                                                              | <b>platinum, at regional storage</b>                                                                                                                                                                            | <b>rhodium, at regional storage</b>                                                                                                                                                                           |

### 5.2.1 PGM, at regional storage, in Ecoinvent

These modules are valid for the consumption of the platinum group metals (PGM) Platinum, Palladium and Rhodium in Europe.

The secondary production is reflected by the recovery of automotive catalysts in Germany according to the actual recycling rate for Europe (Tab. 5.4). It is assumed to be valid for whole Europe.

The primary-production is reflected by the production processes of RSA and RUS according to their market-share. These two countries produce over 90 % of the PGMs. The mix of consumed PGM is assumed to correspond to the production mix shown in chapter 2.1 An average of the share in the global production over the last ten years was chosen (Tab. 5.5). Due to the importance of PGM, transport is assumed to take place by plane, the metal being protected with a case of 50% of its mass.

### Data quality

Allocations will shift with changing market situation. The recycling rate – i. e. the ratio of secondary platinum – may be underestimated, as most of the recovered material does not appear on the market.

**Tab. 5.4 Demand of secondary and primary PGM. Assessment of the share of the secondary production in the world wide demand. The recovery from automotive catalysts has to be added to the total demand to obtain the net demand. For Rh, no region specific figures are available, a world-wide recovery rate is chosen. Values are taken from JohnsonMatthey (2003). Note that the palladium demand in the US is exceptionally small in 2002, resulting in an overestimated ratio of secondary production, which was stable at around 5% of the total consumption until 2001. This is due to the use of stocks by US auto manufacturers in lieu of metal purchases.**

## 5.3 Winning of Primary PGM

This part is mainly based on Hochfeld (1997). Lacking data – mainly on direct emissions to air and to water – was taken from different sources where stated. Because of the big variance between the different production processes due to different ore composition, primary PGM production is represented by the two major sites in Bushveld (ZA) and Noril'sk (RU). The producing companies in these two deposits determine the PGM production within their countries and world-wide.

While the companies in RSA are mainly PGM-dominated, Norilsk Nickel in the Russian Federation earns a large share through Nickel and Copper. Also the ratio of the PGM produced differ between the production in RSA and the one in RUS (see chapter 5.1 above).

For this reasons, the production process in RSA and the one in RUS are treated separately. Their products – the pure metals Pt, Pd, Rh, Ni and Cu – are assembled later according to their market share.

### 5.3.1 Production process

The production process described is valid for both the operations in RSA and in RUS. Differences are stated.

#### Mining

The PGM containing ore is mined underground and transferred to the beneficiation. Widening of the tunnels is mainly done by blasting. The overburden – material, which does not contain PGM-bearing ore – is deposited off-site and is partly refilled into the tunnels.

#### Beneficiation

After mining, the ore is first ground. In a next step it is subjected to gravity concentration to separate the metallic particles from the PGM-bearing minerals. After this first concentration step, flotation is carried out to remove the gangue from the sulfidic minerals. For neutralisation lime is added. In the flotation several organic chemicals are used as collector, frother, activator, depressor and flocculant. Sometimes cyanide is used as depressant for pyrite. Tailings usually are led to tailing heaps or ponds.

#### Metallurgy

The pyrometallurgical step may be divided in three substeps, which can be effected in combination depending on the procedure used. The process is basically the same as in the nickel or copper production. Emitted sulphur dioxide usually is recovered from the off-gas stream producing sulphuric acid.

**Roasting.** The sulphidic ore is roasted at 600 – 700 °C. This oxidises the iron present, dries and pre-heats the ore. Since iron has got a bigger affinity to oxygen than other metals, it gets oxidised to slag releasing the sulphur as sulphur dioxide (Formula 5.1). This reaction is strongly exothermic. Other metals associate again with sulphur to sulphur compounds.

**Smelting.** In this step, the bigger part of the gangue and the iron sulphide is eliminated. The valuable metals concentrate in the matte. Smelting is done at temperatures of 1400 °C. Main reaction is the slagging of the prior formed magnetite ( $\text{Fe}_3\text{O}_4$ ) with the flux (calcite, silicate), according to the formulas 5.2 and 5.3.

The melt is parted from magnetite and now consists of a sulphidic and a oxidic phase. The matte is tapped at 1400 °C and processed in the converting step.

**Converting.** In the converting step, iron sulphide is removed from the low-grade matte by oxidation and slagging. The slag, which contains high levels of metals, is returned to the smelting step for recovery. The final product is high-grade, low-iron nickel – copper matte, which typically contains 20 % S, less than 1 % Fe, and also some precious metals. Converting is a batch operation. Air or oxygen-enriched air is blown through the molten matte to form iron oxides and remove sulphur as sulphur dioxide. The iron oxides combine with added silica flux to form an iron silicate slag (formulas 5.4 and 5.5).

In the processes regarded in this study Pierce-Smith-Converters are used.

### Separation from Non Ferrous Metals

The main accompanying metals in the PGM winning are Nickel and Copper. In the case of the Russian process the winning of these two metals is the main objective. The separation is done in a hydrometallurgical process. In a typical hydrometallurgical process, the concentrate or matte is first leached in a sulphate or chloride solution to dissolve the metals, while the sulphide is oxidised to insoluble elemental sulphur or soluble sulphate. In this way a nickel – copper matte can be treated in a two-stage leach process to produce a copper-free nickel sulphate or nickel chloride solution, and a leach residue enriched in copper. The copper in the copper-rich residue is solubilised by repeated leaching and recovered from solution electrolytically as cathode copper. Nickel is recovered from the purified nickel sulphate or chloride solution either electrolytically as a pure nickel cathode or by chemical reduction with hydrogen to give pure nickel powder. The remaining leach residue contains all PGM, which are extracted in the refining step.

### Refining

The usual starting point for separating platinum group metals or producing compounds and catalysts is an aqueous solution of PGM. Most raw materials can be dissolved in oxidising acids. Once dissolved, there are namely two processes for refining.

**Selective precipitation.** This is the classical process. Separation is based on the principles of analytical chemistry of PGM. In the crystallisation process, the solubility of chloro complexes of the PGM are very important, as is the possibility of altering this solubility. The temperature dependence of this solubility is generally quite large and can be utilised for precipitation. An even more useful phenomenon in separation technology is the effect on solubility of the addition of a common ion, which is utilised in precipitation crystallisation. Conversion of the precipitated salts to their metals is carried out mainly by thermal decomposition at 1000 °C.

**Solvent extraction.** This process is based on the ability of the metals to form together with organic molecules stable complexes. After total dissolution the liquid is treated with a cascade of different specific solvents. Liquid – liquid extraction is characterised by distribution coefficients that vary greatly from element to element. These can usually be further modified by chemical methods. Although separations are generally better than those effected by precipitation, coarse separation by solvent extraction must be further purified.

The principal raw materials are concentrates produced from ores, mattes and slimes from nickel and copper operations. Secondary materials such as spent catalyst or electronic component scrap are also significant sources. PGM refining is complex and individual process stages may have to be repeated to achieve the required purity. Precious metal refineries are complex networks of main and subsidiary processes. It is therefore not possible to identify single process steps and their contribution to emissions and consumptions. The product of this step is the pure platinum group metal.

### 5.3.2 Emissions

#### Mining

Major emissions are due to mineral born pollutants present in effluents. Being underground, the mining has less emissions to air than open pit mining. The major dust sources are on the surface therefore the dust emissions are in the same magnitude like in open pit mining. Rain percolate through overburden and account to metal emissions to groundwater.

#### Beneficiation

Ore handling and processing produce large amounts of dust, containing PM<sub>10</sub> and several metals from the ore itself. Flotation produce effluents containing several organic agents<sup>10</sup> used. Some of these chemicals evaporate and account for VOC emissions to air. Namely xanthates decompose hydrolytically to release carbon disulphide. Tailings effluent contain additional sulphuric acid from acid rock drainage.

#### Metallurgy & Separation from Non Ferrous Metals

**Sulphur dioxide.** In all of the process steps sulphur dioxide is emitted to air. Recovery of sulphur dioxide is only economic for high concentrated off-gas. Therefore recovery is not effected in all process alternatives. SO<sub>2</sub> emissions are by far the most important in the metallurgy.

**Carbon dioxide.** In the beneficiation step, considerable amounts of lime is added to the ore for pH-stabilisation, lime forms later flux in the metallurgical step. Lime decomposes into CO<sub>2</sub> to form calcite.

**Dust.** Dust carry over from the roasting, smelting and converting processes. Particulate emissions to the air consist of metals and thus are often returned to the leaching process after treatment.

**Chlorine.** Chlorine is used in some leaching stages and is produced during the subsequent electrolysis of chloride solution. The chlorine evolved is collected and re-used in the leach stage. The presence of chlorine in wastewater can lead to the formation of organic chlorine compounds (AOX) if solvents etc. are also present in a mixed wastewater.

**VOC.** VOCs can be emitted from the solvent extraction stages. A variety of solvents are used as they contain various complexing agents to form complexes with the desired metal that are soluble in the organic layer.

**Emissions to water.** Metals and their compounds and substances in suspension are the main pollutants emitted to water. The metals concerned are Cu, Ni, Co, As and Cr. Other significant substances are chlorides and sulphates. Wastewater from wet gas cleaning (if used) of the different metallurgical stages are the most important sources. The leaching stages are usually operated on a closed circuit and drainage systems, and are therefore regarded as minor sources.

#### Refining

Also in this step the combustion of sulphur leads to emissions of SO<sub>2</sub>. Nitrogen oxides are produced in significant amounts during acid digestion using nitric acid. Chlorine and HCl can be formed during a number of digestion, electrolytic and purification processes. Chlorine is used extensively in the Miller process and in the dissolution stages using hydrochloric acid and chlorine mixtures respectively. Dust

---

<sup>10</sup> Floating agents consist of collectors (xanthate or aerofloat) and frothing reagent (eg. Methyl Isobutyl Carbinol). Xanthates are a broad class of organic salts formed by treatment of an alcohol with carbon disulfide in the presence of an alkali, potassium ethyl xanthate (KC<sub>3</sub>H<sub>5</sub>S<sub>2</sub>O, CAS No: 140-89-6). Aerofloat is a salt of carbonyldithiophosphoric acids. A widely used frothing reagent is e.g. methyl isobutyl carbinol, CAS: 108-11-2, syn. Methyl Amyl Alcohol.

and metals are generally emitted from incinerators and furnaces. VOC can be emitted from solvent extraction processes, while organic compounds, namely dioxins, can be emitted from smelting stages resulting from the poor combustion of oil and plastic in the feed material. All these emissions are subject to abatement technologies and controlling. Large quantities of effluents contain amounts of metals and organic substances.

### **5.3.3 Waste**

#### **Mining and Beneficiation**

Overburden are deposited close to the mine. Tailings are deposited as piles and in ponds. In both the overburden and the tailings occur acid rock drainage over a long period of time. These effects are handled in the section “Non Ferrous Metal Winning – Auxiliary Processes”, chapter “Disposal of Tailings and Overburden”.

#### **Metallurgy & Separation from Non Ferrous Metals**

The production of metals is related to the generation of several co-products, residues and wastes, which are listed in the European Waste Catalogue. Some of the process specific residues can be reused or recovered in preliminary process steps (e. g. dross, filter dust) or construction (e. g. cleaned slag). Residues also arise from the treatment of liquid effluents, the main residue being gypsum waste and metal hydroxides from the wastewater neutralisation plant. These residuals have to be disposed, usually in lined ponds.

#### **Refining**

Like in the pyro- and hydrometallurgical step quantities of solid residuals are generated, which are mostly recycled within the process or sent to other specialists to recover any precious metals. Final residues generally comprise hydroxide filter cakes (ironhydroxide, 60% water, cat I industrial waste).

### **5.3.4 Primary PGM in ecoinvent**

This module is modelled in two different specifications: “PGM-Production, primary, RSA” for the South African operations and “ PGM-Production, primary, RUS” for the Russian operations. Both modules are similarly modelled, exceptions are mentioned in the text below. The scheme of this multi-output process is shown in Fig. 5.10.

The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.11 - Fig. 5.15. An overview over the module’s general information and metadata is given in Tab. 5.6. The following paragraphs describe calculations, sources and assumptions chosen in this study.

**Fig. 5.10** Scheme of the multi-output process “platinum group metal production, primary” in Ecoinvent. Its jointly produced co-products are “platinum, primary, at refinery”, “palladium, primary, at refinery”, “rhodium, primary, at refinery”, “nickel, primary, couple-production, platinum group metal production” and “copper, primary, couple-production, platinum group metal production”.

**Tab. 5.6 Ecoinvent meta information for the multi-output processes in the primary production of PGM in Russia and South Africa.**

| <b>Included Processes</b>           | The module includes a mining and a beneficiation step with the mining infrastructure and disposal of overburden and tailings. Subsequently it includes the metallurgy step with the disposal of slag, the infrastructure and the separation of the co-products nickel and copper, and the refining step yielding the desired PGM-mix inclusively the refining infrastructure. Production, application and emissions of most agents used in beneficiation and metallurgy are also included.                                                                                                                                                                                                                                                                                                                                 | The module includes a mining and a beneficiation step with the mining infrastructure and disposal of overburden and tailings. | <b>General Comment</b>              | The multioutput-process "PGM-Production, primary" delivers the co-products "platinum, primary, at refinery", "palladium, primary, at refinery", "rhodium, primary, at refinery", "nickel, primary, from platinum group metal production" and "copper, primary, from platinum group metal production" in South Africa (ZA). The module is designed for the use of the metal in technical systems, where it plays a minor role like the use in manufacturing of electronic or technical chemistry using certain catalysts. It is not to be used if the impact of the PGM within the modelled process in scope is considered to be high. In such cases, a more detailed analysis depending on scope and allocation procedures has to be conducted. The data used is mainly based on a LCA study for autocatalysts in Germany. | The multioutput-process "PGM-Production, primary" delivers the co-products "platinum, primary, at refinery", "palladium, primary, at refinery", "rhodium, primary, at refinery", "nickel, primary, from platinum group metal production" and "copper, primary, from platinum group metal production" in the Russian Federation (RU). In such cases, a more detailed analysis depending on scope and allocation procedures has to be conducted. The data used is mainly based on a LCA study for autocatalysts in Germany. |

| Technology Text         | Mining is done underground, followed by beneficiation through flotation where considerable amounts of agents are added. Overburden and tailings are disposed on the mining site and partly refilled. In ZA a electric arc furnace with a Söderberg electrode system and a Pierce-Smith-Converter is used. sulphur dioxide in the off-gas is recovered producing sulphuric acid. The separation of non ferrous metals is done hydrometallurgically, the refining by selective precipitation. Although electricity production in ZA is mainly coal based, the UCTE production mix is inventoried. | Mining is done underground, followed by beneficiation through flotation where considerable amounts of agents are added. Overburden and tailings are disposed on the mining site and partly refilled. In RU a Outokumpu flash furnace followed by a Pierce-Smith-Converter is used. The resulting nickel matte is treated by electroly refining. No recovery of sulphur dioxide in the off gas. The refining is done by selective precipitation, using data from the ZA process as proxy. For electricity mix the UCTE production mix is inventoried |
| Representativeness      | 63%                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             | 23%                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |

### Infrastructure and land use

The production infrastructure used directly for exploration is inventoried within this module, whereas the infrastructure like buildings and land-use for the operation is inventoried in an extern module. The mobile equipment used for exploration like drilling machines, scoop trams and underground trucks is inventoried assessing a standard value for diesel, burned in building machine, i. e. 69.2 kJ per tonne mined raw ore. 2000 m conveyor belts are further assumed with a capacity of 2000 t / h which yields  $2 \cdot 10^{-5}$  m conveyor belt required per tonne mined raw ore. Mining facilities are inventoried as unspecific module according to part II “Non Ferrous Metal Winning – Auxiliary Processes”.

Transformation and occupation of land through direct exploration are assumed with the standard value for non-ferrous metals without heap leaching processes of 0.0025 m<sup>2</sup>/t and 0.075 m<sup>2</sup>/a/t ore mined.

### Mining

In the considered processes the ore is mined underground. The overburden is disposed in piles near the mine (see. Part II “Non Ferrous Metal Winning – Auxiliary Processes”). Based on IPCC (2002) a value of 50 % refilled overburden is assumed. Demand for water was not available for the process in RUS, it was approximated with the value for RSA (of 0.21m<sup>3</sup> / t mined ore). Two third of the water resource use is assumed to be ground water, the rest is surface water. No volume of mining effluents was available, values for water demand were taken. Composition of mining effluents is approximated with values taken from total emissions to water from base metal sites (s. Tab. 5.10). Transport from mine to beneficiation were neglected, it is assumed to take place in direct vicinity of the mine. For diesel use the value of 69.2 kJ per tonne mined raw ore for underground mining given in Hilbrans & Hinrichs (1999) was chosen.

Dust emissions from mining activities are comprised in the beneficiation step below.

Infrastructure of the mine is modelled with the unspecific module “mining infrastructure” from part II “Non Ferrous Metal Winning – Auxiliary Processes”, chapter “Disposal of Tailings and Overburden”. The electricity mix is approximated with the UCTE production mix. For the ore demand an overall

yield of 90 % is assumed, based on the 91 % primary yield in the nickel winning process reported in Hilbrans & Hinrichs (1999).

### Beneficiation

Once the ore is mined, it is ground and conditioned for further concentration. Considerable amounts of lime and flotation agents are added. The separated gangue is disposed in tailings ponds, the concentrated ore is fed to the metallurgy, which is assumed to be on site.

The infrastructure of beneficiation is included in mining infrastructure. Dust emissions comprise additionally the dust emissions due to mining activities. By approximation again electricity production mix for the UCTE is chosen. 50 % of the reported energy consumption is assumed to be used to dry the material, using natural gas, burned in industrial furnace >100kW.

**Lime.** The value for lime – geometric mean – is taken from copper mining where a range from 1 to 4 kg per tonne sulphidic ore is recommended (Krauss et al. (1999)). This value is confirmed by IPPC (2002), Tab. 5.11.

**Reagents.** No information on mass and nature of the floating agents used is available. For copper mining a range of 25 – 300 g collector and 25 – 250 g frothing reagent per ton sulphidic ore is recommended (Krauss et al. (1999)). This is confirmed by the values in Tab. 5.11. Collector and frother are balanced in ecoinvent in their production as unspecified organic chemical. According to NPI (2001) xanthates hydrolytically decompose to 0.53 mg carbon disulphide per mg xanthate. With 189 mg xanthates from Tab. 5.11 this is 102.4 mg carbon disulphide per tonne mined ore.

Activator and Depressants – excluding sodium cyanate – are modelled as unspecific inorganic chemicals, their emission to water is covered by reported emissions from mining sites shown in Tab. 5.10.

For pH adjustment and leaching the value for sulphuric acid was considered with 3.74 kg / t ore mined (Tab. 5.11). As sulphuric acid is an by-product from the metallurgy, it is regarded as burden free. Other acids are neglected.

Since composition and environmental fate of activator, depressant and sulphuric acid is uncertain, reported data for total emissions shown in Tab. 5.10 are taken.

Sodium cyanide is widely used for extracting gold and other metals such as silver, copper and zinc. It is used as leachate and as depressant for certain sulphidic minerals. The environmental fate of cyanide compounds is complex and could not further be quarried. A cyanide recovery of 80 – 90% is reported due to abatement and recovery in the Golden Cross mine in New Zealand (Anonymous (1998a)). Here, a value of 80% is chosen for cyanide-abatement technology. With a reported use of 35 g NaCN per tonne ore mined (Tab. 5.11), this means a direct emission of 3.88 g HCN per tonne ore mined. An overview of the reagents accounted for is presented in Tab. 5.12.

**Effluents.** For the beneficiation effluents of the Russian production no data was available, the same value like RSA are taken (0.35 m<sup>3</sup> / t mined ore). Additional to direct emissions due to the use of chemicals, total emissions to water are chosen according to Tab. 5.10. These values are from base metal sites, thus only an approximation for the real effluent concentrations in the PGM production. It is assumed here that the effluents also include acid rock drainage (ARD). ARD after mine closure is modelled in the module “disposal, sulphidic tailings, off-site”.

**Dust.** A case study in (Anonymous (1998b)) about a projected open cut gold-copper mining and processing facility in Australia predict annual dust emissions between 0.18 kg/t and 0.46 kg/t of dust produced per tonne of ore mined. The prediction was made using the Emission Estimation Technique Manual for Mining (NPI (2001)). The maximum value of 0.46 kg/t is chosen for total dust emissions. Underground mining activities are assumed to generate 80 % of the dust emissions compared to open pit mining (Tab. 5.8) yielding a 0.37 kg dust per t mined ore. According to NPI (2001) the dust com-

position is approximated with values in Tab. 5.7 the average earth's crust. For PM<sub>10</sub> values, the ratio TDS : PM<sub>10</sub> : PM<sub>2.5</sub> was approximated with values from copper ore mining 101.72 : 50 : 5 g / t ore taken from the CEMIP-database<sup>11</sup>, i. e. one tonne emitted dust corresponds to 491.5 kg PM<sub>10</sub> and 49.2 kg PM<sub>2.5</sub> respectively. The dust emissions resulting from underground activities are summed up in Tab. 5.9. In Ecoinvent, for particulates differential classes are used adding up to the total dust emission, i. e. 49.2 kg PM<2.5, 442 kg PM2.5-10 and 508 kg PM>10 per tonne dust.

**Tab. 5.7 Mineral born dust composition depending on rock. Data taken from (NPI (2001)). Values for earth's crust are chosen in this study.**

### Metallurgy and Separation of the non-ferrous metals

The ore concentrate is worked in the typical process steps. In the RSA the sulphidic matte is separated from the slag with an electric arc furnace with a Söderberg electrode system. The ore is poorer in sulphur, resulting in a higher oxygen demand. Air and Oxygen is blown through the matte in a Pierce-Smith-Converter. The cooled matte is ground and magnetically separated. After the separation the PGM-containing part is leached and treated hydrometallurgically. After the electrolytic precipitation, the remaining PGM containing dross is treated in the refinery. The transport to the refinery is assumed to be short and therefore neglected.

In Russia the ore is treated in a Outokumpu flash furnace, where it is roasted and smelted in an auto-genous process (i.e. the heat of the exothermal oxidation of FeS is used in the process, s. 5.3.1). The matte is converted in a Pierce-Smith-Converter. The off-gases of the conversion are not treated. The copper-nickel matte is separated in nickel and copper concentrate, latter being processed further in the near copper facility. The nickel matte is treated with electrowinning (roasting and reduction with coke) and cast into anodes. The remaining PGM containing dross is transferred to the refinery in Krasno-jarsk.

In both processes lime was added in beneficiation which releases now fossil carbon dioxide. Flux is assumed to consist of 50% lime, which also releases carbon dioxide. 0.75 t flux per t matte is reported for copper in Krauss et al. (1999). Burning of 1 t lime ( $\text{CaCO}_3$ ) yields 0.44 t  $\text{CO}_2$ .

Effluent is approximated with demand on water, which was only available for RSA and extrapolated for RUS with 1.4 m<sup>3</sup> per t concentrate input. The effluents are treated. An overview of concentrations in different waste waters after treatment is shown in Tab. 5.14. The values are assembled from different processes in the nickel and copper metallurgy (IPPC (2001)). The data shows high variations, a geometric mean was built to calculate average emissions. To cover the uncertainties, a standard deviation of 10 was chosen for each emission.

The atmospheric emissions are also taken from relative processes from copper and nickel operations observed in IPPC (2001). These emissions are stated as mass per metal produced, therefore it is multiplied with the total metal production of the two considered processes. The distribution of particulate matter is taken from CEPMEIP<sup>12</sup>. The values for sulphur dioxide are stated in Hochfeld (1997). Emissions of sulphur dioxide are one key issue of the metallurgy. In IPPC (2001) much lower values are reported, this seems to be true for European operations. Inco Ltd. states in their environmental report

<sup>12</sup> <http://www.air.sk/tno/cepmeip/>, accessed 01.03.2003

Emissions of 1'500 kg SO<sub>2</sub> / t metal produced in the period between 1997 and 2001. The corresponding values in Hochfeld (1997) are 5'300 for the Russian and 760 kg SO<sub>2</sub> / t for the RSA operations.

In Hochfeld (1997) no specific values for the separation step are reported except for energy, water, dross and the coupled products nickel and copper.

**Tab. 5.13 Emissions to air per tonne produced metal.** Data was taken from similar processes in nickel (A) and copper (B) metallurgy and multiplied with the sum of produced metals (PGM, Ni & Cu). Data is taken from IPPC (2001), the distribution of the particle size is taken from CEPMEIP (C). VOC emission from leaching (D). In this study values for SO<sub>2</sub> emissions are taken from Hochfeld (1997) (E).

### Refining of PGM

The refining step is covered only partially in Hochfeld (1997). Only for the operations in RSA electricity and gas consumption and water demand are reported. These values are added with specific emissions from five large precious metal refineries from IPPC (2001) in Tab. 5.15.. Values for BOD is based on the reported value for COD which is assumed to amount 150% of BOD (Zimmermann et al. (1996)). Values for TOC are calculated using the standard procedure approximating the organic matter with C<sub>6</sub>H<sub>12</sub>O<sub>6</sub> (Frischknecht et al. (2003b)). Particle distribution is assessed with values for open hearth exhausts from steel foundries after ESP control from EPA (1998). Transports are included in emissions to air.

Precious metal refineries recover simultaneously several precious metals from a variety of raw materials. No information about the way of allocation is available, an allocation by mass is assumed, i. e. emissions of a tonne precious metal correspond to 1 tonne PGM, notwithstanding any possible co-product.

For the operation in RUS the same burden is assumed. The PGM-containing matte has to be transported from Norsil'sk 1500 km up Yenisey river to Krasnojarsk for refining.

**Tab. 5.15** Reported emissions to air and water from 5 large refinery processes. Data taken from IPPC (2001). Annual operation hours assumed with 6000 h / a. Values for BOC, TOC and DOC calculated

### Data quality

The uncertainties are assessed using the pedigree matrix (see Frischknecht et al. (2003b)). For detailed results compare the different flows and the ecoinvent meta information.

**Mining.** Data for major mass fluxes are satisfactory, while the emissions in to water may be overestimated due to different system boundaries of reported effluent volume from Hochfeld (1997) and total effluent emissions reported in IPPC (2001).

**Beneficiation.** Like in mining, the emissions to water can be overestimated. The emissions from tailings are assessed in an extern module, which itself contains rough assumptions of a global overburden and tailings composition and a simplified disposal scenario. Emissions though can vary considerably from case to case, it is not evident, whether the calculated emissions meet the reality.

**Metallurgy.** Process data is satisfactory and valid for over 90 % of the PGM. The main emissions dominating possibly the whole PGM process is sulphur dioxide, which is reported for both processes and found to be consistent with other data Krauss et al. (1999), IPPC (2001) and Hilbrans & Hinrichs (1999). Poor data are available on composition and fate of solid waste, an overestimation may occur due to higher recycling and reuse rates than assumed in this work.

**Separation of the non-ferrous metals.** Main data on energy and mass fluxes is satisfactory, while data on direct emissions due to hydrometallurgical processes is poor. Namely chlorine emissions can be considerable, generating both HCl emissions to air and AOX emissions to water – emissions which are not assessed in this work due to lacking data.

**Refining.** No data on many specific emissions in to the air was available. Namely high-impact solvents and complexants are not registered. Due to the closed-loop strategies of such refineries, only small emissions of problematic substances are expected.

## 5 System Characterisation

**Fig. 5.11 Flows for “PGM-Production, primary – Part mining” and their representation in the ecoinvent database. Values in column “Mean value RUS” correspond to the Russian PGM production, the values in the column “Mean value RSA” correspond to the South African PGM production. Uncertainty assumptions are identical for both modules. Values relate to the production of 1 kg PGM.**

**Fig. 5.12** Flows for “PGM-Production, primary – Part beneficiation” and their representation in the ecoinvent database. Values in column “Mean value RU” correspond to the Russian PGM production, the values in the column “Mean value ZA” correspond to the South African PGM production. Uncertainty assumptions are identical for both modules. Values relate to the production of 1 kg PGM.

**Fig. 5.13** Flows for “PGM-Production, primary – Part metallurgy” and their representation in the ecoinvent database. Values in column “Mean value RU” correspond to the Russian PGM production, the values in the column “Mean value ZA” correspond to the South African PGM production. Uncertainty assumptions are identical for both modules. Values relate to the production of 1 kg PGM.

Fig. 5.14 Flows for “PGM-Production, primary – Part separation” and their representation in the ecoinvent database. Values in column “Mean value RU” correspond to the Russian PGM production, the values in the column “Mean value ZA” correspond to the South African PGM production. Uncertainty assumptions are identical for both modules. Values relate to the production of 1 kg PGM.

**Fig. 5.15** Flows for “PGM-Production, primary – Part refining” and their representation in the ecoinvent database. Values in column “Mean value RU” correspond to the Russian PGM production, the values in the column “Mean value ZA” correspond to the South African PGM production. Uncertainty assumptions are identical for both modules. Values relate to the production of 1 kg PGM.

## 5.4 Winning of Secondary PGM

As shown in chapter 2, considerable amounts of PGMs originate from secondary production. Since the intended module is a consumer-mix valid for European consumers, the secondary production of PGM represents the collection, beneficiation and refining of PGM containing scrap in the European Region. The process in concern is mainly based on (Hochfeld (1997)) and describes the secondary production in Germany, which will stand for the whole European region. Further more only data on recycling of automotive catalysts are available. Since it can be assumed, that by far the most part of PGM recycling origins from recovered automotive catalysts, this study focuses solely on recycling of automotive catalysts and neglect other sources of secondary PGMs.

### 5.4.1 Production process and infrastructure

The production process can mainly be described in the three steps: Collection, Beneficiation and Refining. Information on production process is taken from (Hagelücken (2001a)).

**Collection.** Spoiled automotive catalysts are bought by specialised enterprises from different origins. Part of it originates from scrap dealer recycling end-of-life cars. Further more during the cars operating phase, defective catalysts are exchanged in garages. The third sources is the production waste, i. e. defective catalysts which do not reach market. In most cases, there are fix agreements between the different supplier and the intermediary trade. Although the trade with PGM containing scrap is risky. Motor car manufacturer built up their own internal recycling systems with their contractor garages and gained access to exchanged catalysts.

**Beneficiation.** The catalysts are dismantled and then sold to refining companies. Refineries too have long-term contracts with the intermediary trade.

**Refinery.** The scrap first is shredded and then hydrometallurgically or pyrometallurgical processed. The direct hydrometallurgical path dissolves the scrap with strong acids for following precipitation. This has the handicap of effluents and larger amounts of dross and PGM losses. Therefore it is rarely used nowadays. In the pyrometallurgical process, the scrap is smelted and the ceramic wafer is slagged. The PGMs are concentrated in the collector metal, usually copper. Low-content PGM scrap is often smelted together with other non-ferrous metal matte. This is cheap, but effects a high loss in PGM. The collector matte from the furnace then is treated hydrometallurgically by re-precipitation as described in 5.3.1. In this step usually production scrap from other industries (glass, chemical laboratories) is joined. The overall PGM-yield is 98 % for platinum and 85 % for rhodium – no data on recovery of palladium was available.

### 5.4.2 Emissions and Waste

#### Air

Emissions during collection and beneficiation are gases from transportation and dust from dismantling. Also in this step the combustion leads to emissions of SO<sub>2</sub>. Nitrogen oxides are produced in significant amounts during acid digestion using nitric acid. Chlorine and HCl can be formed during a number of digestion processes. Chlorine is used extensively in the dissolution stages using hydrochloric acid and chlorine mixtures respectively. Dust and metals are generally emitted from incinerators and furnaces. VOC can be emitted from solvent extraction processes, while organic compounds, namely dioxins, can be emitted from smelting stages resulting from the poor combustion of oil and plastic in the feed material. All these emissions are subject to abatement technologies and controlling.

**Water**

During collection and beneficiation no serious emissions are reported. Effluents from refining contain considerable amounts of metals and organic substances.

**Waste**

Solid residues from pyrometallurgical step are usually re-used in copper facilities, final residues generally comprise hydroxide filter cakes.

**5.4.3 Secondary PGM in ecoinvent**

This module in ecoinvent describes the collecting of automotive catalysts in Germany, the dismantling of the catalysts and the pyrometallurgical processing followed by a hydrometallurgical purification step. The data is mainly taken from Hochfeld (1997) and IPPC (2001).

The scrap is assumed to be transported over 600 km by lorry, further emissions are neglected. The origin of the automotive catalysts is burden-free. For dismantling an average electricity-input of 50 kWh/t is assumed in Hochfeld (1997).

The metallurgical step consists of an arc-furnace. Values for electricity-input and lime and copper addition are reported in Hochfeld (1997) for one big German enterprise, but no direct specific emissions. These values are taken from IPPC (2001), representing the same refining-step as in the primary production. Data on the hydrometallurgical electrolysis still lacks and is assessed with data on refining from the module “Primary Production of PGM”. The emissions from Tab. 5.15 used there and the respective energy use per tonne PGM from Hochfeld (1997) are also chosen for secondary production.

The layout of the modules with general flow information, remarks, sources, values uncertainty information are shown in Fig. 5.16. An overview over the meta information is given in Tab. 5.16.

**Data quality**

The uncertainties are assessed using the pedigree matrix (see Frischknecht et al. (2003b)). For detailed results compare the different flows and the ecoinvent meta information.

Based on the literature no satisfactory process data was available. The hydrometallurgical step is approximated with emissions and energy use of the refining in the primary production.

**Tab. 5.16 Ecoinvent meta information for the multi-output processes in the secondary production of PGM in Europe from recycled automotive catalysts.**

| GeneralComment               | This module describes the collecting of autocatalysts in Germany, the dismantling of the catalysts and the pyrometallurgical processing followed by a hydrometallurgical purification step. The multioutput-process "PGM-Production, secondary, RER" delivers the co-products "platinum, secondary, at refinery", "palladium, secondary, at refinery" and " rhodium, secondary, at refinery". The smelter slag disposal is inventoried as disposal of inert material, thus neglecting potentially important (but unknown) heavy metal emissions. |

## Comments on version 2.0

This part corresponds to the original report in Althaus et al. (2004) that has been updated with the changes reported in Frischknecht et al. (2006). The changes were implemented with v1.2 which corrected the amount of resource required in the chromite dataset by factor two. Additionally to the reported errors the emissions of solids, PAH and chromium to water had been corrected by a factor 1E-3 in the dataset “ferrochromium, at plant” as compared to the data in version 1.3.

The flow names in the tables displaying unit process data have not been updated consistently to reflect the name changes with version 2.0.

No changes were made in version 2.1 compared to version 2.0.

Chapter “6 Cumulative Results and Interpretation” of the original report has been deleted for the current update.

## Summary

This part describes the production of chromite, ferrochromium and metallic chromium from cradle to consumer in Europe. Chromite is used for the production of chemicals and refractories. Ferrochromium is used as alloy for steel and chromium is mainly used for special iron free alloys (superalloys), e.g. for high-temperature exposed components in chemical and petrochemical industries.

Mining, beneficiation and the different metallurgical processes are inventoried vertically aggregated because of difficulties to clearly allocate some of the flows to one single step and because the intermediate steps would not make sense in another context. The Figures in this report however contain the available information to the single steps.

Since no chromium is recycled within the chromium industry but directly to the foundries of the stainless steel industry, no secondary chromium is considered in this study.

# 1 Introduction

This part describes the production of ferrochromium and metallic chromium from cradle to consumer in Europe. Inventory data for the ferrochromium production is taken mainly from Adelhardt & Antrekowitsch (1998) together with background data from IPPC (2002), IPPC (2001), Papp (1994) and EEA (1999).

Like many metals used as alloying element, chromium is recycled from steel-scrap in foundries directly as secondary alloys. Depending on their composition, these secondary chromium containing materials are used together with ferrochromium as secondary source for chromium. In this study, only the primary material ferrochromium and metallic chromium is considered. Secondary chromium sources – i.e. alloys from recycled steel scrap – have to be inventoried in the respective production module, e.g. in the stainless steel production.

The main environmental impact by producing refractory metals is metal containing dust and hard metal powder as well as fume from the smelting processes for instance by producing chromium metal. Dust emissions occur from storage, handling of raw materials and products and the furnace operation, where both stack and fugitive emissions play an important role. Hydrogen fluoride, which is used in several processes, is highly toxic and needs therefore to be handled very carefully to avoid any health problems for the plant staff. Another environmental impact of the production of hard metals is the toxicity of metal compounds such as chromium.

Over the last 15 to 20 years, the world pattern of the ferro-alloy market has deeply changed:

- The consumption of the developing countries has vastly increased with the development of their steel production;
- Their production has even more increased because they have taken a growing share of the traditional markets of the industrialised countries, where the steel production was stagnant or growing at a slow rate.
- The ferro-alloy industry is facing a growing proportion of imports, at first from the new industrialised countries and in recent years from the countries of East Europe and the CIS (former Soviet Union).

As a consequence, EU ferro-alloy production has been submitted to a difficult competition that results in a decreasing trend of the total amount of ferro-alloys produced. Although the last years showed some stabilisation, even a slightly increase of the production, the European industry remains very sensitive.

## 2 Reserves and Resources of Chromium

Metals are a special class of materials. They are not consumed but rather used during a product life cycle. When recovered the properties are theoretically identical to those in the raw material. The metal can be re-used in another product life cycle, provided that its concentration makes a recovery economic. The recovered metal is referred to as secondary metal, whereas the metal originating directly from the ore is referred to as primary metal. In LCIs these two types – primary and secondary metal – are often differentiated because they bear a different ecological burden.

### 2.1 Primary Chromium

Of the many minerals that contain chromium only the chromium spinels are of economic importance. Chromite is found in stratiform and podiform deposits.

- Stratiform deposits (seam-like) Layers up to a meter thick; e.g. Bushveld Igneous Complex (South Africa), the Great Dyke (Zimbabwe) and the Stillwater Complex (United States).
- Podiform deposits (shaped like sacks or tubes). Range in size; Ural Mountains, Albania, Zimbabwe, and the Philippines.

Generally, richer lumpy Cr bearing ores have been preferred for smelting, whereas those with  $\text{Cr}_2\text{O}_3$  content less than 40 % have been used in refractories. The internal texture of the chromite ore bodies varies widely. The closest chromite crystal packing results in the formation of massive ores containing 75 - 85 vol% of chromite.

Production and resources are presented in Tab. 2.1. The largest chromite-ore-producing countries (India, Kazakhstan, and South Africa) accounted for about 76% of world production. South Africa alone accounts for more than 45% of world production and has been the major supplier of chromium in the form of chromite ore and ferrochromium to western industrialised countries (USGS (2003)).

### 2.2 Secondary Chromium

The major end use of chromium is in stainless steel, and this is the major form in which chromium is recycled. Ferrochromium is added to iron at steel-producing plants to make the iron-chromium alloy stainless steel.

Stainless steel scrap can substitute for ferrochromium as a source of chromium. Scrap is generated during the manufacturing process (new scrap) and as a result of recycling obsolete equipment (old scrap). Scrap from these sources is collected and sorted by grade (i.e., chemical composition) in scrap yards. Scrap brokers play a role in moving material from where it is recovered to where it is consumed. The steel industry consumes stainless steel scrap as a source of chromium and nickel. Thus chromium units are recycled when stainless steel is reused. A study of domestic stainless steel found that its average chromium content is about 17% (USGS (2003)). Papp (2001) reports a recycling rate of 20% for the US in 1998 with a domestic (primary) production of 144 kt and a consumption of old (75.3 kt) and new scrap (28.6 kt) of total 103.9 kt, imports of 263 kt and releases of stock of 37.2 kt to meet the consumption of chromium in the fabrication of stainless steel of 522 kt and exports of 22.5 kt (all values in chromium contained).

The typical raw materials for the production of secondary ferro alloys are the following residues generated mainly within the production of stainless steel:

- Electric arc furnace (EAF) filter dust
- Converter filter dust
- All kind of scale fines
- Shot blasting dust
- Grinding dust

Since no chromium is recycled within the chromium industry but directly to the foundries of the stainless steel industry, no secondary chromium is considered in this study.

**Tab. 2.1 Mine production and reserves of chromium in 2001. “Reserves” is referred to as “the part of the reserve base which could be economically extracted or produced at the time of determination”, while “Reserve base” denotes “that part of an identified resource that meets specified minimum (...) criteria related to current mining and production practices” (USGS (2003)).**

|                              | Mine production  |                                 | Reserves | Reserve base |

## 3 Characterisation of the Materials

Based on the raw material chromite, various chromium containing materials are produced for the use in a broad field of applications.

### 3.1 Chromite ore

Chromite [53293-42-8] is a spinel  $\text{FeO} \cdot \text{Cr}_2\text{O}_3$ . In nature it is a mixture described by the formula  $(\text{Fe}^{2+}, \text{Mg})\text{O} \cdot (\text{Cr}, \text{Al}, \text{Fe}^{3+})_2\text{O}_3$ . The theoretical  $\text{Cr}_2\text{O}_3$  content in chromite would be 67.9% (46.5% Cr), but in reality this value ranges between 25% and 60%  $\text{Cr}_2\text{O}_3$  (17% - 40.8% Cr). The chromium content in chromite is  $2 \cdot 52 / 152 = 68.4\%$ , Adelhardt & Antrekowitsch (1998) calculated a world-wide average content of 37.3% Chromite (25.5% Cr) in raw ore. Chromite ore rarely contains more than 50 %  $\text{Cr}_2\text{O}_3$ ; other minerals such as  $\text{SiO}_2$  can also be present. Typical composition of some important metallurgical chromite ores are summarised in Tab. 3.1.

A high Cr : Fe ratio is advantageous to produce an alloy with high chromium content. Chromite ores are classified as follows:

- Ores rich in chromium:  $> 46\% \text{Cr}_2\text{O}_3$ , Cr : Fe  $> 2 : 1$ ; for the production of ferrochromium
- Ores rich in iron:  $40 - 46\% \text{Cr}_2\text{O}_3$ , Cr : Fe  $< 2 : 1$ ; for the production of charge chrome and for the chemical industry
- Ores rich in aluminium:  $> 60\% (\text{Cr}_2\text{O}_3 + \text{Al}_2\text{O}_3)$ ,  $> 20\% \text{Al}_2\text{O}_3$ ; for refractories

Metallurgical-grade chromite ores are classified as hard lumpy or friable lump types, fines, and concentrates. Concentrates are produced by mechanical upgrading of lean ores or fines. In the production of high-carbon ferrochromium, generally a lumpy type of chromite ore is necessary. About 80 % of chromite ores in the western world are fines ( $< 10 \text{ mm}$ ). Therefore, efforts have been made to agglomerate these. Fines of chromite ores can be used to produce low-carbon ferrochromium.

### 3.2 Chromium Metal

At room temperature Chromium [7440-47-3] is resistant to ordinary corrosive agents, which explains its use as an electroplated, protective coating. It dissolves in non-oxidising mineral acids, such as hydrochloric and sulphuric acids, but not in cold aqua regia or nitric acid, which passivate the metal. At elevated temperature it reacts with halogens, silicon, boron, nitrogen, oxygen, and carbon. Chromium and chromium-rich alloys are brittle at room temperature (Downing et al. (1997)).

Chromium metal is a metallurgical industry product. It is produced by one of two processes: electrolysis or aluminothermic reduction. Chromium metal produced by these processes is essentially the same differing only in amount of various trace chemical constituents. The largest production of chromium metal is by the aluminothermic reduction process (ICDA).

Selected physical properties of elemental chromium are given in Tab. 3.2.

### 3.3 Ferrochromium

In the metallurgical industry, the principal product is ferrochromium, a mixture of chromium and iron with varying amounts of other chemical constituents. Ferrochromium is further classified by its carbon content as high-carbon, medium-carbon, or low-carbon ferrochromium. By far, the largest production

of ferrochromium is the high-carbon variety. It is the major source of chromium for the production of steel alloys.<sup>1</sup>

Ferrochromium is a master alloy of iron and chromium, containing 45 – 95 % Cr and various amounts of iron, carbon, and other elements. The ferrochromium alloys are classified by their carbon content and are known by their French names because basic work in this field was carried out mainly in France:

- High-carbon ferrochromium (HC ferrochromium) with 4 – 10 % C, "ferrochrome carbure"
- Medium-carbon ferrochromium (MC ferrochromium) with 0.5 – 4 % C, "ferrochrome affiné"
- Low-carbon ferrochromium (LC ferrochromium) with 0.01 – 0.5 % C, "ferrochrome suraffiné"

The mechanical and chemical properties of steel can be improved by alloying it with ferrochromium. Chromium combined with nickel gives stainless steel excellent chemical resistance (Downing et al. (1997)). Some physical properties of different ferrochromium alloys are given in Tab. 3.3

Tab. 3.1 Analyses of some chromite ores, metallurgical grade (Downing et al. (1997))

| Compound                       | Chromite ore, wt% |                  |           |             |              |

## 4 Use / Application of Material

Chromium has a wide range of uses in metals, chemicals, and refractories. However, in this study only ferrochromium is of further importance. A schematic overview is given in the following Fig. 4.1.

Fig. 4.1 The chromium life cycle process from mining to commercial, scheme taken from ICRA's homepage at <http://www.chromium-asoc.com/>

### 4.1 Chromite ore

Chromite ore is the central intermediary product in the chromium industry. From it the three main product groups are made: ferrochromium, chromium chemicals and refractories. Chromite is used directly in the refractory industry to make bricks, mortar, and ramming and gunning mixes. Chromite enhances thermal shock and slag resistance, volume stability, strength and is used mainly in the ferrous and non-ferrous industry, cement industry and glass manufacturing. In foundries for certain applications chromite is used as moulding sand, for which chromite sand with more specific properties is applied.

In 1994 around 8% of the chromium produced was used in the refractory industry, while 80% went into the production of ferrochromium and 12% into the chemical industry (Adelhardt & Antrekowitsch (1998)).

In the refractory industry, the principal products are shaped and unshaped refractories. Refractories are used to line metallurgical furnaces that produce steel or copper alloys. They are also used in the heat exchange section of glass making furnaces and in cement kilns. These refractories are consumed in the process of making steel, copper, glass, and cement, but they are not part of those products. The annual

chromite production for 2002 is given in Fig. 4.2<sup>2</sup>. Further details on use of refractories in the glass industry can be found in Hischier (2003)

The consumption of chromium was reported in Papp (1994) to be 30 t Cr / Mt cement and 450 t Cr / Mt copper in the cement and copper industry respective. Adelhardt & Antrekowitsch (1998) reports the use of 2 and 5 kg refractories per tonne of converter and electric steel respectively.

After use, refractories are recuperated in order to remove hexavalent chromium, which is built under high temperature and oxidising conditions (Adelhardt & Antrekowitsch (1998)).

## 4.2 Chromium Chemicals

In the chemical industry, the principal product is sodium dichromate. Sodium dichromate is used both as feed material for the production of other chromium chemicals and as process material for the surface treatment of metals. The use of chromite by the chemical industry is substantially smaller than that of the metallurgical industry. Chemicals made from or along with sodium dichromate, are industrial products including chromic acid, chromic oxide, and potassium dichromate. The uses of chromium chemicals are quite diverse and include metal finishing, leather tanning, pigment production, and wood preservation<sup>2</sup>.

Chromium compounds are used in numerous fields. In addition to the applications mentioned, chromates have long been used in printing as an aid in photomechanical reproduction. For some time, chromium dioxide has been a component of magnetic tapes for information storage. About 12 % of the chromium used world-wide is in the form of chromium chemicals (Adelhardt & Antrekowitsch (1998)).

Directly or via several intermediate stages, sodium dichromate ( $\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2 \text{H}_2\text{O}$ ; CAS 7789-12-0), is the starting material for the production of all chromium compounds and pure chromium metal. For further details on use and production see Althaus et al. (2003)

Chromium(III) oxide (Chromium Hydroxide) ( $\text{Cr}_2\text{O}_3$ ; CAS 1308-38-9), finds widespread application as a green pigment resistant to atmospheric conditions and heat. In addition, it is used as a colorant in glass products and printing inks, as a vitrifiable pigment in the ceramics industry, and as a polishing agent because of its considerable hardness.

Chromium(IV) Oxide (Chromium Dioxide) ( $\text{CrO}_2$ ; CAS 12018-01-8) is used as a magnetic pigment. So far no other uses have achieved any significance.

Chromium trioxide ( $\text{CrO}_3$ ; CAS 1333-82-0), also known as chromic acid anhydride or chromic acid, is made by the reaction of sodium dichromate with sulphuric acid. Electroplating is the most important field of application of chromium(VI) oxide. Numerous mixtures containing chromium trioxide are on the market; these "compounds" often contain hexafluorosilicates which improve the properties of the chromium coatings. Chromic acid solutions are also used for passivating zinc, aluminium, cadmium, and brass. Proprietary mixtures predominantly contain additions of fluoride, nitrate, and phosphate ions. Other uses for chromic acid are in the production of chromium dioxide and in wood preservation.

## 4.3 Chromium Metal

Pure chromium metal, produced by electrolytic or aluminothermic processes, is used for alloying non-ferrous engineering materials. Chromium metal is a major source of chromium for non-ferrous alloys that exclude iron, such as certain superalloys. The most common materials are nickel-based and cobalt-based alloys, most of which are used as high temperature alloys (Downing et al. (1997)).

---

<sup>2</sup> <http://www.chromium-asoc.com/publications/frame.html>

The aerospace industry is the major source of demand for chromium metal in the form of superalloys, which are manufactured and consumed mostly in North America and Europe. World chromium metal demand was increasing by 1'000 t/yr over the last years. Chromium metal production is estimated at 22'000 t in 2001; 21'000 t in 2000; and 20'000 t in 1999. The trend is expected to continue. Besides aerospace industry, the major end use industries are gas turbine, and petrochemical (USGS (2003)).

## 4.4 Ferrochromium

Ferrochromium is used principally as a master alloy to produce chromium-containing steel and cast iron. Chromium in steel imparts corrosion resistance because of the formation of a thin, continuous, impervious chromium oxide film on the steel surface.

Most ferrochromium is used to manufacture stainless steel. Martensitic grades with ca. 13 % Cr are used for applications such as knives, whereas ferritic grades with 18 – 22 % Cr are used as deep-drawing sheets. Austenitic CrNi steels exhibit especially good corrosion (acid) resistance and are used for equipment in the chemical industry as well as for food-processing machinery. The annual production of ferrochromium dropped from 5'720'000 t in 2000 to 4'680'000 in 2001 (USGS (2003)).

Ferrochromium is classified usually into two major groups: low-carbon and high-carbon ferrochromium. It is used as a source of chromium by the steel industry and as a source of chromium for non-ferrous alloys that permit some iron content.

High-carbon ferrochromium is one of the chromium industry's most important products with a share of 91% in the production. Low-carbon ferrochromium production accounts to 9% of the total and dropped from 792'738 t in 1988 to 413'079 t in 2001; an annual compound growth rate of 0.95 over the time period (USGS (2003)).

Technological changes in the consuming industry permit the substitution of high-carbon ferrochromium for low-carbon ferrochromium. The substitution is desirable because low-carbon ferrochromium production is more expensive than high-carbon ferrochromium production.

The annual ferrochromium production for 2002 is given in Fig. 4.3.

## 4.5 Chromium Alloys

Stainless steel is composed of two broad categories – austenitic and ferritic. The names are related to the molecular structure of the steel but also identify which grades require nickel (austenitic) and which do not (ferritic).

The only true chromium-based alloys that have been developed and used commercially are a few chromium – nickel alloys. These materials contain 50 – 60 % chromium; the remaining percentage is nickel, with either niobium (columbium) or titanium specified as carbon and nitrogen scavengers. These alloys, often referred to as superalloys, are used in the construction of high-temperature exposed components in chemical and petrochemical industries (Downing et al. (1997)).

The most widely known chromium containing alloy is the stainless steel AISI 302 (Fe/Cr18/Ni8), which contains 18 % Cr and 8 % Ni. A small amount of molybdenum further improves the acid resistance. Heat-resistant steel (24 – 26 % Cr and 19 – 21 % Ni) is used in power stations for steam boilers and heat exchangers; superalloys based on nickel or cobalt (ca. 30 % Cr) are used for gas turbine parts.

The annual production of stainless steels for 2002 is given in Fig. 4.4.

Tab. 4.1 Uses of chromium compounds (Anger et al. (1997))

| Branch of industry    | Product                           | Use                                                    |
|-----------------------|-----------------------------------|--------------------------------------------------------|
| Building industry     | chromium(III) oxide               | pigment for coloring building materials                |

## 5 System Characterisation

This study focuses on the main processes in the chromium production as shown in Fig. 4.1. As shown in chapter 4 Use / Application of Material no secondary production of chromium has to be considered, since the recycling of chromium occurs directly into the foundries in the form of re-melted alloys from chromium containing scrap.

**Fig. 5.1** Scheme of the chromium production system considered. The study focuses on the production of high-carbon ferrochromium, which is based on chromite. Chromite itself is used in different other modules in ecoinvent like “portachrom, at plant” Hischier (2003), “sodium dichromate, at plant” Althaus et al. (2003) and in the cement production. Metallic chromium is won from two different processes. Values shown are in tonnes of chromium contained and are based on USGS (2003) and Adelhardt & Antrekowitsch (1998).

Tab. 5.1 Ecoinvent meta information for the processes for the production of chromite and ferrochromium.

| Name                         | chromite, ore concentrate, at beneficiation                                                                                                                                                                                                                                                                                                                                                                                                             | ferrochromium, high-carbon, 68% Cr, at plant                                                                                                                                                                                                                                                                                                                                                                                                                       |

| Included Processes           | The module includes a mining and a beneficiation step with the mining infrastructure and disposal of overburden and tailings (see part II "Auxiliary Processes").                                                                                                                                                                                                                                                                                       | The module includes the pre-treatment of the ore and the reduction to high-carbon ferrochromium. No secondary production considered, since secondary chromium is recycled to the foundries and has to be inventoried in the respective module, i.e. when casting the final raw material in the stainless steel production.                                                                                                                                         |

| General Comment              | The module describes the production of chromite in 1994 for a world-wide production average. It is designed for the use of chromite as intermediary product in the production of ferrochromium, dichromate and refractories. Process data is taken mainly from a material flow analysis for the consumption of chromium compounds in Germany. The ore concentrate produced has a content of 30.7% Cr (44.9% Cr <sub>2</sub> O <sub>3</sub> ) by weight. | The module describes the production of chromite in 1994 for a world-wide production average. It is designed for the use of chromite as intermediary product in the production of ferrochromium, dichromate and refractories. This module does not consider secondary sources of chromium. Process data is taken mainly from a material flow analysis for the consumption of chromium compounds in Germany. Results are used as a proxy for the European situation. |

| Dataset Version              | 2.0                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            | 2.0                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| Included Processes           | The module includes the transportation of high-carbon ferrochromium to Europe. No secondary production considered, since secondary chromium is recycled to the foundries and has to be inventoried in the respective module, i.e. when casting the final raw material in the stainless steel production.                                                                                                                                                                                                                                                                                                       | Both aluminothermic production and electrolysis are aggregated in this module. It comprises the production of Cr <sub>2</sub> O <sub>3</sub> as intermediary product, the aluminothermic process, the transport of the raw materials to Europe and the electrolysis. No emissions are taken into account. No secondary production considered, since secondary chromium is recycled to the foundries and has to be inventoried in the respective module, i.e. when casting the final raw material in the stainless steel production. |
| Amount                       | 1                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | 1                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

| General Comment              | The module describes the consumption of chromite in Europe in 1994. It is designed for the use of chromite as intermediary product in the production of ferrochromium, dichromate and refractories. This module does not consider secondary sources of chromium. Process data is taken mainly from a material flow analysis for the consumption of chromium compounds in Germany. Results are used as a proxy for the European situation. Disposal of smelter slag is inventoried as disposal of inert material, thus neglecting the potentially important (but quantitatively unknown) heavy metal emissions. | The module describes the chromium metal consumed Europe in 1994. It is designed solely for the use of the metal as alloying element in super-alloys (Ni-Cr). Usually stainless steels are made from ferrochrome and not from chromium metal. Chromium is considered to be made by aluminothermic process (75%) and electrolysis (25%). This module does not consider secondary sources of chromium. The general data quality is not satisfying, due to a lack of information.                                                       |

## 5.1 Exploitation of chromite

### 5.1.1 Production process and infrastructure

**Mining.** Chromite ores are usually mined underground. Adelhardt & Antrekowitsch (1998) report an estimated share of 71% underground mining activities in the mine production in 1994 considered in their study, representing 78% of the total production. Of a surveyed part of 52% of the total world production, 69% of the chromite originated from stratiform deposits.

**Beneficiation.** After mining, the ore is first crushed in several stages with jaw and / or cone crushers, and then subsequently ground with rod and or ball mills and finally screened for classification. In a second step the classified material is subjected to gravity concentration to separate the metal-bearing particles from the unwanted minerals. For this drum separators and de-watering screens for lumps are used and cone separators and a high-gradient magnetic separator for fine material. No flotation is done. Chromite yields vary in a range from 65% to 85% (Adelhardt & Antrekowitsch (1998)).

### 5.1.2 Emissions & Waste

#### Mining

The major emissions are due to mineral born pollutants in the effluents. Open cut mining generates large quantities of dust, which contains elevated contents of metals. Rain percolates through overburden and leads to metal emissions to groundwater. Overburden is deposited close to the mine.

#### Beneficiation

Ore handling and processing produce large amounts of dust, containing PM<sub>10</sub> and several metals from the ore itself. Tailings are deposited as piles and in ponds. Since the tailings are not sulphidic, no acid rock drainage (ARD) occurs. In the tailings material the most significant contents are Cr and Ni, which occur as insoluble compounds and are considered not to cause any negative effects IPPC (2002).

### 5.1.3 “chromite, at beneficiation” in ecoinvent

The module describes the world-wide average production of chromite in 1994. It is designed for the use of chromite as intermediary product in the production of ferrochromium, dichromate and refractories. Process data is taken mainly from Adelhardt & Antrekowitsch (1998), which conducted a material flow analysis for the consumption of chromium compounds in Germany. Results are used as a proxy for the European situation. Emission factors are mainly taken from IPPC (2002) and Anonymous (1998b).

The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.2 and Fig. 5.3. Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 13. The following paragraphs describe calculations, sources and assumptions chosen in this study.

#### Infrastructure and resource use

The mobile equipment used for exploration like drilling machines, scoop trams and underground trucks is inventoried with the diesel consumption reported in Adelhardt & Antrekowitsch (1998). The used module “diesel, burned in building machine” includes the infrastructure of the machines. Use of conveyor belt was assessed according Tab. 5.2.

The world average chromite content after beneficiation amounts to 30.7% (44.9% Cr<sub>2</sub>O<sub>3</sub>), a yield from mining and beneficiation of 81% can be calculated (Adelhardt & Antrekowitsch (1998)).

According to part IX, chapter 2.1 of this report (Non Ferrous Metal Winning – Auxiliary Processes) no direct land use for underground mining (71%) is inventoried. Land use for open pit mining (29%) per tonne of ore is assessed with  $0.0025 \text{ m}^2/\text{t}$ . Thus the average land transformation for mining (underground and open pit) is  $0.000725 \text{ m}^2/\text{t}$  ore and the occupation is  $0.0218 \text{ m}^2/\text{a/t}$  ore (a lifetime of 30 years is assumed). Mining facilities are inventoried as unspecific module according to part IX (Non Ferrous Metal Winning – Auxiliary Processes).

**Tab. 5.2 Assumptions for infrastructure used in underground mining exploration. As lifetime ten years are estimated, and 5000 working hours yearly.**

| Action      | Share | Machine        | Throughput   | Unit       | Infrastructure       |
|-------------|-------|----------------|--------------|------------|----------------------|
|             |       |                | t / lifetime | Length (m) | m / t ore mined      |
| Open pit    | 29 %  | Conveyor belts | 100'000'000  | 10'000     | $1 \cdot 10^{-4}$    |
| Underground | 71 %  | Conveyor belts | 100'000'000  | 2'000      | $2 \cdot 10^{-5}$    |
| Mix         |       |                |              |            | $4.32 \cdot 10^{-5}$ |

## Mining

According to Adelhardt & Antrekowitsch (1998) 71 % of the chromite world production originates from underground mines. The overburden is disposed in piles near the mine, 1.77 kg per kg ore mined. The standard module for disposal of non-sulphidic overburden was chosen, which includes the land use and transformation through the disposal. No overburden is refilled according to Adelhardt & Antrekowitsch (1998). In the world-wide average  $0.35 \text{ m}^3/\text{t}$  crude ore of the pit water is used for the beneficiation. The remaining pit water is not inventoried as output but its emissions are inventoried together with the emissions of the beneficiation step.

## Beneficiation

Once the ore is mined, it is ground and classified. No flotation is needed in beneficiation. The separated gangue is disposed in tailings ponds, the concentrated ore is fed to the metallurgy, which is assumed to be on-site. The respective standard module “disposal, non-sulphidic tailings, off-site” is chosen (c.f. part IX (Non Ferrous Metal Winning – Auxiliary Processes), chapter 2.3 (Disposal of Tailings and Overburden)).

The beneficiation infrastructure is approximated with a similar facility from the aluminium production (c.f. part 1 (Aluminium)). Dust emissions comprise additionally the dust emissions due to mining activities. Hilbrans & Hinrichs (1999) assume for the nickel mining a share of 60% hydroelectricity due to the operations high and constant energy demand. The same assumption is made for chromite. The value comprises the electricity demand of the mining, which is expected to be small compared to the beneficiation.

**Steel:** The steel input (abrasion) for milling is documented in IPPC (2002) for a single Finnish chromite mine (Kula) and amounts to  $300 \text{ g} / \text{t}$  ground ore. The mill (jaws, balls, etc.) consists of special austenitic manganese steel of Hadfield grade, which is approximated with chromium steel in the inventory.

**Water use & effluents:** Water use is documented in Adelhardt & Antrekowitsch (1998) and is inventoried in this study as originating from river without pumping activities. Total emissions to water are chosen according to Tab. 5.3. These values are reported from a chromite site in Finland (Kula) and recommended values. The reported value of  $150 \text{ mg} / \text{l}$  COD is assumed to amount to 150% of BOD (Zimmermann et al. (1996)). Values for TOC are calculated using the standard procedure in

Frischknecht et al. (2003) approximating the unknown organic matter with the simplified formula for organic matter  $C_6H_{12}O_6$ . This gives 58.7 mg / l TOC and DOC respectively.

**Dust:** A case study in (Anonymous (1998a)) on a projected open cut gold-copper mining and processing facility in Australia predict dust emissions between 0.18 kg/t and 0.46 kg/t of dust produced per tonne of ore mined. The prediction was made using the Emission Estimation Technique Manual for Mining (NPI (2001)). The maximum value of 0.46 kg/t is chosen for total dust emissions, the value for underground mining is assessed with 80% of this amount. The dust composition is approximated with the chromite ore composition from Tab. 3.1. For  $PM_{10}$  values, the ratio TSP :  $PM_{10}$  :  $PM_{2.5}$  was approximated with values from manganese ore mining 101.72 : 50 : 5 g / t ore taken from the CEMIP-database<sup>3</sup>, i.e. one tonne emitted dust corresponds to 492 kg  $PM_{10}$  and 49 kg  $PM_{2.5}$  respectively. The airborne emissions resulting from mining and beneficiation activities are summed up in Tab. 5.4. In ecoinvent, for particulates differential classes are used adding up to the total dust emission, i.e. 49 kg  $PM_{<2.5}$ , 442 kg  $PM_{2.5-10}$  and 508 kg  $PM_{>10}$  per tonne of total dust.

### Data quality

**Mining:** Data for major mass fluxes are satisfactory, while the emissions into water may be overestimated due to different system boundaries of reported effluent volume from Adelhardt & Antrekowitsch (1998) and total effluent emissions reported in IPPC (2002) and Anonymous (1998b).

**Beneficiation:** Like in mining, the emissions to water can be overestimated. No emissions from the disposal of the tailings are modelled since no information about such emissions is available.

| <sup>a)</sup> Inventoried in Ecoinvent as trivalent chromium ion. Hexavalent chromium is assumed to oxidise quickly to trivalent chromium in the course of abatement and aeration.<br><sup>b)</sup> chromite is no sulphidic ore, therefore no use of this substance and consequently no emission is assumed<br><sup>c)</sup> Maximum values relates to the whole range of base metal extraction. This specific emission is not assumed to be of importance in chromite exploitation. |                      |                       |                   |

**Tab. 5.4 Emissions to air resulting from mining activities per tonne mined ore. Values for total dust emission are taken from Anonymous (1998a), partition of fractions of particulate matter from the CEMIP-database (mining of manganese ore), the dust composition correspond to the average chromite ore from "3.1 Chromite ore" in this study.**

| Emission to air | Unit      | Emission per tonne mined ore |

## 5.2 Winning of high-carbon ferrochromium

As seen in Fig. 5.1, high-carbon ferrochromium accounts for the major part of chromium consumption. Although the traditional type for steel manufacturing was the high-chrome low-carbon ferrochrome. Much more economic and hence of higher importance for the industry nowadays is high-carbon ferrochrome. Since the introduction of the AOD process (Argon-Oxygen-Decarburisation) the steel industry prefers high-carbon ferrochrome, which originates predominantly from stratiform deposits rich in iron (Adelhardt & Antrekowitsch (1998)).

### 5.2.1 Production process and infrastructure

High-carbon ferrochromium is produced almost exclusively by direct reduction of chromite ores with carbon (coke, coal, or charcoal) in large, three-phase submerged arc furnaces with 10 - 50 MVA capacity, corresponding to 15 000 – 60 000 t/a of ferrochromium production.

The oxides of iron and chromium present in the chromite can be readily reduced at high temperature with carbon. Because of the tendency of chromium to form carbides, a carbon-containing alloy is always obtained. Carbides with higher carbon content formed initially at lower temperature react at higher temperature with  $\text{Cr}_2\text{O}_3$  and form carbides with lower carbon content; finally, reduction of  $\text{SiO}_2$  – in the case of silicochromium production – starts at higher temperature. The basic reaction can be formalised as follows:

Electric arc furnaces work continuously with an input of chromite, coke, dolomite, silica and bauxite or other  $\text{Al}_2\text{O}_3$  containing materials. Metal and slag are tapped in regular intervals. The submerged arc furnaces use Söderberg electrodes where the electrode may be formed by hot paste, briquettes, blocks or paste cylinders.

The coke rate is calculated on the basis of the stoichiometric requirement of the oxides and on the amount of dissolved carbon in the alloy; allowance is made for some combustion at the top of the furnace and for reaction with moisture. The slag composition is important to produce metal of desired quality and to maintain smooth furnace operation.

Because more than 80 % of chromite ore mined in the western world is finer than 10 mm, agglomeration processes have been adopted to provide good burden porosity in the electric arc furnaces. In some ferrochromium plants, fines and lumpy ores are blended in ratios between 1 : 1 and 4 : 1. (Downing et al. (1997)).

In older plants with quite small furnaces the off-gas containing considerable amounts of CO is burned in the top and cleaned thereafter. Modern plants with semi-closed furnaces do not need to burn the CO. This results in a lower off-gas volume – factor 10 to 20 – and the possibility of re-using the gas as secondary fuel in other processes. By using a closed, sealed furnace the volume of the off-gas can be reduced by even a factor of 50 – 75. The smelting charge can be pre-heated in a shaft or rotary kiln by using the CO-gas from the smelting process. The yield of chromium amounts from 85% to 95%.

Triggered by enhanced demand of chromium in the metallurgical industry, bigger plants and new processes recently evolved. These processes - Outokumpu, Showa Denko, Krupp-CODIR and plasma - are discussed in detail in Adelhardt & Antrekowitsch (1998). They feature much lower specific energy demand and higher yield (around 90%).

Fluxing agents, e.g., quartzite or alumina (corundum or bauxite) and lime, are charged with the burden for slag formation.

Slag that contains metal is also crushed and the metal content recovered by means of slag-metal separation. Recovered slag-free lump metal can be sold, while slag contaminated metal and fines are generally recycled to the smelting process.

An example of a high-carbon ferrochromium production process using a closed submerged electric arc furnace is shown in Fig. 5.4.

Fig. 5.4 Example of a High-carbon ferrochrome production process using a closed submerged electric arc furnace (IPPC (2001)).

## 5.2.2 Emission

**Air:** The main environmental impact by producing ferro-alloys is the emission of dust and fume from the smelting processes. Dust emissions occur as well from storage, handling and the pre-treatment of raw materials where fugitive dust emissions play an important role. Depending on the raw material and the process used other emissions to air are  $\text{SO}_2$ ,  $\text{NO}_x$ ,  $\text{CO}$ -gas,  $\text{CO}_2$ , polycyclic aromatic hydrocarbon (PAH), VOCs, and volatile metals. The formation of dioxins in the combustion zone and in the cooling part of the off-gas treatment system (de-novo synthesis) may be possible.

**Water:** Water emissions are produced from cooling, granulation and other processes and site related effluents. The wastewater generated by a wet cleaning abatement system plays also an important role.

## 5.2.3 Waste

Process residues and by-products with a significant amount is slag, filter dust and sludge and spent refractories. These materials are already recycled and reused to a large extent where it is possible. Rich slag, that means slag with a relatively high proportion of metal oxides, is used as raw material in other ferro-alloy productions.

## 5.2.4 Ferrochromium, high-carbon, 68% Cr, at plant in ecoinvent

This part is mainly based on Adelhardt & Antrekowitsch (1998). General process description was taken from (Fabian (1997)), process specific emissions from IPPC (2001), IPCC (1996), EPA (1998) and EC (2002).

Adelhardt & Antrekowitsch (1998) differentiates between old (submerged electric arc furnace) processes and the newer (Outokumpu, Showa Denko, Krupp-CODIR and plasma), and assumes a share of 50% each.

The module describes the world average production mix for ferrochromium in 1994 based on Adelhardt & Antrekowitsch (1998). It is designed for the use of the metal as alloying element. The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.5 (inputs) and Fig. 5.6 (output). Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 13. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one kg of ferrochrome with an average chromium content of 68%.

**Infrastructure and transport:** It is assumed that the bauxite used as flux is transported by ship over 20'000 km, the additives chromite, bauxite, silica, coke, slag and the disposals slag and cake by lorry over 50 km.

**Energy:** Adelhardt & Antrekowitsch (1998) calculates an average gross electricity demand of 3533 kWh containing smelting (4000 kWh and 2500 kWh for old and new process respectively), de-dusting (74.8 kWh), crushing & screening (0.68 kWh) and production of the electrode (207 kWh), assuming the new and the old process to be equal in production volume. In this study, the production of the electrodes is inventoried in a special module and has to be subtracted from this value, resulting in an average electricity consumption of 3325 kWh / t Cr. An overview over different in- and output values from different sources is given in Tab. 5.5

**Emissions to air:** Air emissions are taken from various sources, they are summarised and discussed in Tab. 5.6.

**Water use and emissions:** Water use for European ferrochrome production is reported in IPPC (2001), the average of 20 m<sup>3</sup> per tonne is chosen resulting in 10 m<sup>3</sup> of effluent (volume of process water). The effluent has to be treated in a communal waste-water treatment plant, a process which is inventoried separately in the chosen module "treatment, sewage, unpolluted, to wastewater treatment, class 3". Emissions to water inventoried are based on reported values after internal process water treatment and before waste water treatment plant (Tab. 5.7).

<sup>a)</sup> No abatement  
<sup>b)</sup> ESP facility  
<sup>c)</sup> The average of the IPCC study is preferred to the value in BREF  
<sup>d)</sup> Averages of EPA values are chosen for world wide mix.  
<sup>e)</sup> Values given as percent in dust (TSP), resulting in emissions of 3.17 kg Cr<sup>III</sup> and 79.2 g Cr<sup>VI</sup> per tonne ferrochrome.  
<sup>f)</sup> SNAP-Code 040309, „Other - Installations for smelting and casting of non ferrous metals“  
<sup>g)</sup> Value taken from ferrosilicon production

**Tab. 5.7 Emissions to water in the production of 1 tonne ferrochromium. The reported values are before final waste-water treatment and after internal abatement including lamella thickener, vacuum filter and a sand and carbon filter. Based on the chosen values, final emissions into water are calculated.**

| Emission to Water<br>(before treatment) | Unit   | BREF |      | This Study        |
|-----------------------------------------|--------|------|------|-------------------|
|                                         |        | Low  | High |                   |
| TSS                                     | kg / t | 5    | 10   | 7.5 <sup>a)</sup> |
| Cr                                      | mg / t | 10   | 20   | 15 <sup>b)</sup>  |
| PAH                                     | mg / t | 300  | 1000 | 650 <sup>c)</sup> |
| dry cake                                | kg / t | 200  | 400  | 300 <sup>d)</sup> |

<sup>b)</sup> Zimmermann et al. (1996) reports a transfer-coefficient for chromium into water of 51.4%. This gives an emission after treatment of 7.7 mg Cr / t  
<sup>a)</sup> An elimination of 95% TSS assumed, resulting in an emission after treatment of 375 g TSS / t  
<sup>c)</sup> Based on Zimmermann et al. (1996) transfer coefficients of 10% to water is assumed, resulting in emissions of 65 mg PAH / t. Emissions to air as CO<sub>2</sub> and NMVOC are neglected.  
<sup>d)</sup> Dry cake results from internal waste-water treatment. In this study it is assumed to be disposed as inert waste to an inert material landfill.

## Data quality

Process data from Adelhardt & Antrekowitsch (1998) is satisfactory and valid for over 74 % of the world-wide primary chromium production. Process specific emissions to air and water had to be taken from another source covering another geography and technology. Nevertheless the overall quality of the modules is fair.

## 5. System Characterisation

### 5.2.5 Ferrochromium, high-carbon, 68% Cr, at regional storage in ecoinvent

The module describes the ferrochromium consumed Europe in 1994. The situation for Germany described in Adelhardt & Antrekowitsch (1998) is taken as proxy for Europe. It is designed for the use of the metal as alloying element. The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.7. Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 13. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one tonne of ferrochrome consumed in Europe with an average chromium content of 68%.

Adelhardt & Antrekowitsch (1998) examined the transport means and distances of ferrochromium from different supplying countries to Germany (Tab. 5.8 and Tab. 5.9). Since imported chromite is determined for the production of low-carbon ferrochrome, no import of chromite is considered for the production of high-carbon ferrochrome, i. e. all of the high-carbon ferrochrome consumed in Europe is considered to be imported. Besides transport services no further impacts – such as energy consumption through reloading and transferring – are inventoried.

## 5.3 Production of metallic chromium

Chromium metal can either be made from chromite ore and concentrates by carbo- and metallothermic reductions or by electrolysis from chromic acid. In order to get chromic acid the chromite ore is roasted with sodium carbonate followed by a leaching process with sulphuric acid to produce sodium chromate that can further be transformed to chromic acid IPPC (2001).

### Aluminothermic process

The usual method of reduction by carbon is inapplicable to the reduction of refractory oxides and ores. The products commonly covered under this title are usually required to be low in carbon and they are avid carbide formers. Also, no conventional refractories would stand up to the long reduction times at the high temperatures required. For such products, advantage is taken of the high temperatures achieved and the rapidity of metallothermic reactions using reactive metals, notably Al (Hall (1997)).

The thermic process uses aluminium as a reducing agent for chromium hydroxide. The charge is weighed and loaded into a bin, which is taken to an enclosed room to mix the contents. The firing pot is prepared by ramming refractory sand mixed with water around a central former. After ramming the firing pot, the inner surface is coated with a weak binder solution and dried under a gas fired hood before being transferred to the firing station. The raw material mix is automatically fed at a controlled rate into the firing pot, where the exothermic reaction takes place. When the metal has solidified following the reaction, the firing pot is removed and transferred by crane to a cooling conveyor. On removal from the cooling conveyor (by crane), the firing pot is placed on a stripping bogie for transfer to a stripping booth. Inside the closed booth, the pot casing is hoisted off the solidified metal/slag. The slag is separated from the Chromium metal “button” and sent to a despatch storage area. Water is used to reduce button temperature to below 100 °C. After cooling the metal button is transferred to other departments on site for cleaning, breaking, crushing and grinding to achieve the desired product size (IPPC (2001)).

### Electrolysis

In the electrolytic process normally high carbon ferrochrome is used as the feed material which is then converted into chromium alum by dissolution with sulphuric acid at temperatures at about 200 °C. After several process steps using crystallisation filtration ageing, a second filtration and a clarifying operation the alum becomes the electrolyte for a diaphragm cell. Chromium is plated onto stainless steel cathodes until it attains a thickness of ca. 3 mm. The process is very sensitive. The additional degassing (heating at 420 °C) stage is necessary because the carbon content of the electrolytic chromium is sometimes too high for further industrial applications. The cooled chromium metal is fragmented with a breaker prior to crushing and drumming. The generated slag can be reused as refractory lining or sold as abrasive or refractory material. IPPC (2001).

### 5.3.1 Emissions & Wastes

The general manufacturing of refractory metals normally takes place at high temperatures. The environmental impact on air, water and land can be classified as follows.

**Emissions to air:** Dust and fume emissions from smelting, hard metal and carbide production; other emissions to air are ammonia (NH<sub>3</sub>), acid fume (HCl), hydrogen fluoride (HF), VOC's and heavy metals.

**Emissions to water:** Overflow water from wet scrubbing systems; Wastewater from slag and metal granulation; Blow down from cooling water cycles.

**Wastes:** Dust, fume and sludge; Slag.

### 5.3.2 “Chromium, at regional storage” in Ecoinvent

The module describes the chromium metal consumed in Europe in 1994. The situation for Germany described in Adelhardt & Antrekowitsch (1998) is taken as proxy for Europe. It is designed solely for the use of the metal as alloying element in superalloys (Ni-Cr). The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.8. Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 13. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one tonne of chromium consumed in Europe.

11'150 t chromium metal was produced 1989 by aluminothermic processes, whereas 4'350 t came from electrolytic winning (Adelhardt & Antrekowitsch (1998)). The share in electrolytic processes is not rising significantly; a production level of 5'000 t in 2003 is assumed. This gives a share of the preferred aluminothermic process of 75 %.

#### Aluminothermic process

The aluminothermic process uses chromium hydroxide ( $\text{Cr}_2\text{O}_3$ ) as raw material and aluminium powder as reducing agent. It is the preferred production process with an assumed share of 75 %. Hall (1997) describes the fundamental reaction practice as follows:

Heat required for products at 2000 °C amounts to 540 kJ.  $\text{Al}_2\text{O}_3$  (H2273-H298) is 356 kJ, 2 Cr (H2273-H298) is 184 kJ. According to this, there is a heat balance, so there should be a satisfactory result. However, it is found in practice that 125 kJ extra heat are required, provided by Al plus  $\text{K}_2\text{Cr}_2\text{O}_7$ . The extra heat reaction can be formalised as follows

The energy required to heat the additional  $\text{K}_2\text{O}$  is assumed to be 200 kJ, which leads to a stoichiometric factor of  $(1768 - (184 + 2 \cdot 356 + 200))/125 = 5.4$ . An addition of  $5.4 \cdot (1) + (2)$  gives:

which gives the final stoichiometry. Hence per kg chromium 442 g  $\text{K}_2\text{Cr}_2\text{O}_7$ , 600 g Al and 1.23 kg  $\text{Cr}_2\text{O}_3$  is necessary. Adelhardt & Antrekowitsch (1998) gives a yield of 89 % - 92 %, an average of 90.5 % is chosen.

Assuming a  $\text{Cr}_2\text{O}_3$  content of 44.9% in the chromite concentrate and a yield of 90% in the  $\text{Cr}_2\text{O}_3$  production from chromite, for the 1.23 kg  $\text{Cr}_2\text{O}_3$  3.05 kg chromite concentrate are required.

$\text{CaO}$  is not used as flux in Cr manufacture as it spoils the slag for use in refractories and calcium chromite is a stable compound.  $\text{CaF}_2$  often is used as its low melting point of 1418 °C assists in promoting a smooth reaction. The amount used is often 1 – 2 % of the total charge, never more than 5 % (Hall (1997)). However, HF emissions are not considered in this study due to the lack of data.

For transportation the information in Adelhardt & Antrekowitsch (1998) is used. It is assumed, that the chromium is produced in Europe and the chromite is imported in the same transportation mix as illustrated in Tab. 5.8.

Adelhardt & Antrekowitsch (1998) states that the energy needed for the production of  $\text{Cr}_2\text{O}_3$  is 85 MJ per tonne chromium content, 250 MJ / t-Cr for the aluminothermic winning and 25 MJ / t-Cr for the refining. The 250 MJ / t-Cr comprise the production of the aluminium powder, which amounts to 185 MJ / t-Al according to EAA (2000). With this, a sum of 317 MJ per tonne metallic chromium is required: 153 MJ for the  $\text{Cr}_2\text{O}_3$ -production (1.23 kg with 68% chromium contained), 139 MJ for the aluminothermic process and finally 25 MJ for the refining. The production of aluminium and dichromate are not included in this figures and inventoried in the respective modules. The energy in the

$\text{Cr}_2\text{O}_3$ -production is assumed to originate from natural gas. For the aluminothermic process and refining a share of 60% hydroelectricity and 40% UCTE-mix is assumed.

### **Electrolytic process**

The rest of chromium (25 %) is still produced from ferrochrome in an electrolytic process. No information on material input and output were available. The energy demand is stated in Adelhardt & Antrekowitsch (1998) to be 18 kWh, whereas Papp (1994) reports 22.7 kWh per tonne chromium citing industry sources in 1993. In this study the higher value of 22.7 kWh (=81.8 MJ) was chosen. Considerable amounts of hydrogen and ammonia ought to be used for reduction and leaching, but no detailed information is available. Hence none of these emissions are taken in account.

## Comments on version 2.0

This part corresponds to the original report in Althaus et al. (2004). None of the changes reported in Frischknecht et al. (2006) regarded the datasets described in this part. Therefore no alteration of the original text was made for version 2.0.

No changes were made in version 2.1 compared to version 2.0.

Chapter “6 Cumulative Results and Interpretation” of the original report has been deleted for the current update. Note that the flow names in the tables displaying unit processes have not been updated to reflect the name changes with version 2.0. This namely affects the designation of transportation service flows.

## Summary

This chapter describes the production of ferromanganese and metallic manganese from cradle to consumer in Europe. Inventory data for the production is taken mainly from Adelhardt & Saiger (1999) together with background data from IPPC (2002), IPPC (2001) and Wellbeloved et al. (1997).

Only the primary production is inventoried because manganese is mainly used in alloys and recycled in them.

Ferromanganese is to be used for alloying steel while manganese is used for alloying aluminium or for direct use (e.g. sputtering)

# 1 Introduction

This chapter describes the production of ferromanganese and metallic manganese from cradle to consumer in Europe. Inventory data for the production is taken mainly from Adelhardt & Saiger (1999) together with background data from IPPC (2002), IPPC (2001) and Wellbeloved et al. (1997).

Like many metals used as alloying element, manganese is recycled from steel-scrap in foundries directly as secondary alloys. Depending on their composition, these secondary manganese containing materials are used together with ferromanganese – and manganese ore – as secondary source for manganese. In this study, only the primary material ferromanganese and metallic manganese is considered. Secondary manganese sources – i.e. alloys from recycled steel scrap – have to be inventoried in the respective production module, e.g. in the steel production.

Over the last 15 to 20 years, the world pattern of the ferro-alloy market has deeply changed:

- The consumption of the developing countries has vastly increased with the development of their steel production;
- Their production has even more increased because they have taken a growing share of the traditional markets of the industrialised countries, where the steel production was stagnant or growing at a slow rate.
- The ferro-alloy industry is facing a growing proportion of imports, at first from the new industrialised countries and in recent years from the countries of East Europe and the CIS (former Soviet Union).

As a consequence, EU ferro-alloy production has been submitted to a difficult competition that results in a decreasing trend of the total amount of ferro-alloys produced. Although the last years showed some stabilisation, even a slightly increase of the production, the European industry remains very sensitive.

## 2 Reserves and Resources of Manganese

Metals are a special class of materials. They are not consumed but rather used during a product life cycle. When recovered the properties are theoretically identical to those in the former raw material. The metal can be re-used in another product life cycle, provided that its concentration makes a recovery economic. The recovered metal is referred to as secondary metal, whereas the metal originating directly from the ore is referred to as primary metal. In LCIs these two types – primary and secondary metal – are often differentiated because they bear a different ecological burden.

### 2.1 Primary Manganese

Manganese is contained in many minerals, of which approximately 250 can be regarded as true manganese minerals. The major ores, generally with manganese contents above 35 %, are hydrated or anhydrous oxides. The silicates and carbonates occur to a lesser extent. Economically significant manganese deposits are all of sedimentary origin, having been dissolved from crystalline rocks and deposited as the oxide, hydroxide, or carbonate. The major manganese minerals are listed in Tab. 2.1 (Wellbeloved et al. (1997)). Wad is the term given to the soft, earthy, hydrous mixture of manganese and iron oxides of variable manganese content.

The most important manganese ore deposits are located in the Republic of South Africa, the Soviet Union, Australia, Gabon in West Africa, and Brazil. The deposits in India and Mexico are of declining importance, and the majority of the production is consumed domestically (Tab. 2.2).

Another potentially important source of manganese are the deep-sea nodules located in certain areas of the ocean floor. Its exploitation has not yet been proven economic.

### 2.2 Secondary Manganese

The major end use of manganese is in iron and steel, and this is the major form in which manganese is recycled (ISS, iron and steel scrap). A smaller fraction ends up as aluminium beverage cans, which are recycled too. On a weight basis, aluminium beverage cans typically consisted 75% of bodies made from alloy 3004 and 22% of lids made from alloy 5182 in the US in 1994. The nominal manganese content of alloy 3004 is 1.1%, and that of alloy 5182 is 0.35% (USGS (1998)).

Manganese scrap enters the production process in the furnaces of the steel industry in the form of alloys with a specific composition. USGS (1998) reports a recycling rate of 37% and a manganese loss in the recycling process of 52% for the US in 1998.

Since no manganese is recycled within the primary industry but directly to the foundries of the iron and steel industry, no secondary manganese is considered in this study.

Tab. 2.1 Manganese minerals of economic importance (Wellbeloved et al. (1997))

| Mineral       | Formula                                                                        | Theoretical Mn content, % | Relative density |
|---------------|--------------------------------------------------------------------------------|---------------------------|------------------|
| Pyrolusite    | $\beta\text{-MnO}_2$                                                           | 63.2                      | 5                |
| Braunite      | $\text{Mn}^{2+}\text{Mn}_6^{3+}\text{SiO}_{12}$                                | 66.6                      | 4.7–4.9          |
| Manganite     | $\gamma\text{-MnOOH}$                                                          | 62                        | 4.3              |

## 3 Characterisation of the Materials

Manganese ore is the raw material for several manganese alloys and manganese chemicals and finally manganese metal. Generally, high-carbon ferromanganese and silicomanganese are produced from a blend of manganese-containing ores, and in the case of silicomanganese, slags and silica are added.

### 3.1 Manganese ore

Typically, only ores containing a minimum of 35 % Mn are regarded as manganese ores. Ores containing 10 – 35 % Mn are categorised as ferruginous manganese ores, and iron ores with 5 – 10 % Mn are referred to as manganiferous ores (Wellbeloved et al. (1997)). Pyrolusite (a mineral form of manganese dioxide), braunite (an oxysilicate), and rhodochrosite (a manganese carbonate) are among the minerals more commonly found in manganese ores (USGS (1998)).

The three most important areas of application of manganese ores and the specific requirements, are as follows (Wellbeloved et al. (1997)):

1. Metallurgical grade ore for the iron and steel industry, which generally contains 38 – 55 % Mn. The phosphorus content should preferably be below 0.1 %, and the concentrations of  $\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2$ ,  $\text{CaO}$ ,  $\text{MgO}$ , and S are important. The manganese/iron ratio is critical; a 7.5 : 1 ratio, for example, is required for a standard ferromanganese alloy with 78 % Mn.
2. Battery grade ore, containing 70 – 85 %  $\text{MnO}_2$  (44 – 54 % Mn). The ore should generally contain less than 0.05 % of metals more electronegative than zinc, such as copper, nickel, cobalt, and arsenic. The suitability of manganese dioxide for use in batteries depends on a number of factors, including the crystal structure, surface area, pore size distribution, particle shape and size, electrical conductivity, surface conditions, chemical composition, and structure defects.
3. Chemical grade ore whose specifications vary considerably depending on the end use. Included in this category are feed stocks for electrolytic manganese and manganese dioxide, manganese chemicals, colorants and, in the Republic of South Africa, an oxidant in uranium extraction.

Compositions of ores of some major operations are given in Tab. 3.1 and Tab. 3.2.

### 3.2 Manganese Metal

Manganese is a silver-grey metal, resembling iron. It is hard and very brittle, and its primary uses in a metallic form are as an alloying, desulphurising, and deoxidising agent for steel, cast iron, and non-ferrous metals. Due to its high tendency to oxidise, annealing colours are often evident. Manganese belongs to group 7 and period 4 of the periodic table with an atomic number of 25 and atomic mass of 54.94. Six isotopes have been produced, of which only  $^{55}\text{Mn}$  is stable. The other isotopes,  $^{51}\text{Mn}$ ,  $^{52}\text{Mn}$ ,  $^{54}\text{Mn}$ ,  $^{56}\text{Mn}$ , and  $^{57}\text{Mn}$ , have half-lives ranging from 46 min to 310 d. Manganese exists in four allotropic forms:  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ . It has a low vapour pressure (Wellbeloved et al. (1997)).

Selected physical properties of manganese are given in Tab. 3.3.

### 3.3 Ferromanganese

A number of manganese-containing ferroalloys are manufactured which are used largely in the mild steel, foundry, and stainless steel industries. The principal manganese ferroalloys and their typical components are high-carbon ferromanganese (78% manganese, 7% carbon, balance mostly iron) and silicomanganese (66% manganese, 17% silicon, 2% carbon). The names and typical compositions of these alloys are given in Tab. 3.4.

| Spiegeleisen                          | 16-28          | <6.5     | 11-45   |

## 4 Use / Application of Material

Metallurgical applications account for most manganese consumption, of which 85% to 90% in the US has been going to steel-making and about 8% to the manufacture of dry cell batteries. The preponderance of the manganese used for making batteries is now electrolytic manganese dioxide (EMD) because usage of natural battery ore has declined greatly. The manufacture of manganese chemicals, such as potassium permanganate, and agricultural use of manganese in animal feed and plant fertiliser as oxide, sulphate, and oxysulphate together account for another 5% of use. These patterns of domestic use are typical for other industrialised countries having well-developed steel industries (Fig. 4.1).

In non-metallurgical uses, the most common valences for manganese are two and four, and oxygen is the main element with which manganese is combined. Accordingly, the mineral and commodity chemistry of manganese centers on such compounds as manganous oxide ( $\text{MnO}$ ), manganese dioxide ( $\text{MnO}_2$ ), manganese carbonate ( $\text{MnCO}_3$ ), and manganese sulphate ( $\text{MnSO}_4$ ) (USGS (1998)). The predominant products and their production route is illustrated in Fig. 4.2.

### 4.1 Manganese ore

Manganese ore is the central intermediary product in the manganese industry. From it the three main product groups are made: ferromanganese for the use in the steel industry (over 90%) and manganese compounds for the use in the chemical industry and battery manufacture. As illustrated in Fig. 4.1, battery or chemical grade ore are processed into manganese metal or manganese oxides, whereas from metallurgical grade ores manganese alloys are made. Silicomanganese is made predominantly from high-silica ore.

### 4.2 Manganese Metal

The largest application of manganese metal in the metallurgical sector is in aluminium alloying, particularly the alloys from which items such as beverage cans and siding are made. The predominant form in which manganese is added to molten aluminium is briquette (typically 75% manganese, 25% aluminium) made by compacting powders of the two metals. In 1990, the amount of manganese metal used by the steel industry was about one-third as much as by the aluminium industry. Because use of manganese metal, as opposed to ferroalloy, is a relatively expensive way of adding manganese, the metal is added in steel making as a “trimming addition” to adjust final composition, particularly when an increase in carbon content is not permissible. Today the world market is in excess of  $140 \times 10^3$  t/a. The compositions of some alloys are given in Tab. 4.1.

### 4.3 Ferromanganese and Silicomanganese

Generally, high-carbon ferromanganese and silicomanganese are produced from a blend of manganese-containing ores, and in the case of silicomanganese, slag and silica are added. USGS (2003) estimates that manganese unit consumption in steel making in the US in 2001 amounts to 5.4 kg manganese per tonne raw steel. The use of manganese alloys depends strongly on the steel industry. Tab. 4.2 gives an overview over the end uses of ferromanganese in the U.S. in 2001.

Fig. 4.1 Summary of manganese products and their process routes (Wellbeloved et al. (1997)).

Fig. 4.2 Simplified diagram for the production of key manganese chemicals (Jones (1994)).

## 5 System Characterisation

This study focuses to the main processes in the manganese production. As shown in chapter 4 “Use / Application of Material” no secondary production of manganese has to be considered, since the recycling of manganese occurs directly into the foundries in the form of re-melted iron and steel scrap.

**Fig. 5.1 Scheme of the manganese production system considered and applications of its products after Adelhardt & Saiger (1999). Percentages relate to the total manganese contained. In this study the processes for ore exploitation, production of high-coal ferromanganese and manganese metal are considered.**

According to Fig. 5.1, the following modules cover the manganese production system for the use of manganese in its main application areas “steel industry” as ferronickel and as manganese metal in different specific uses. They are summarised in Tab. 5.1.

- “manganese, concentrate, at beneficiation” Fig. 5.2, Fig. 5.3
- “ferromanganese, high-coal, 74% Mn, at regional storage” Fig. 5.4, Fig. 5.5
- “manganese, pure metal, at regional storage” Fig. 5.6

Tab. 5.1 Ecoinvent meta information for the processes for the production of ferromanganese and manganese metal.

| Name                         | manganese, concentrate, at beneficiation                                                                                                                                                                                                                                                                                      | ferromanganese, high-coal, 74.5% Mn, at regional storage                                                                                                                                                                                                                                                                                                                                                                                | manganese, pure metal, at regional storage                                                                                                                                                                                                                                                                                                                                                                                     |

| Included Processes           | The module includes a mining and a beneficiation step with the mining infrastructure and disposal of overburden and tailings (see part II "Auxiliary Processes").                                                                                                                                                             | The module includes the reduction to high-carbon ferromanganese. No secondary production considered, since secondary manganese is recycled to the foundries and has to be inventoried in the respective module, i. e. when casting the final raw material in the steel production.                                                                                                                                                      | The module production by electrolysis from ore and by electrothermic process from ferromanganese and slag. Transportation to Europe is only partially considered.                                                                                                                                                                                                                                                              |

| General Comment              | The module describes the production of manganese ore in 1994 for a world-wide production average. It is designed for the use of manganese ore as intermediary product in the production of ferromanganese and manganese metal. For the use of this module in the battery manufacture, the data quality may not be sufficient. | The module describes the consumption of ferromanganese in Europe in 1995. It is designed for the use of the metal as alloying element. This module does not consider secondary sources of manganese. Process data is taken mainly from a material flow analysis for the consumption of chromium in Germany. Results are used as a proxy for the European situation. This module may be used as proxy for the silicomanganese production | The module describes the consumption of manganese metal in Europe in 1994. It is designed solely for the use of the metal in special applications like sputtering or as alloying element. This module is explicitly not to be used as alloying element in bulk iron or steel industry. It does not consider secondary sources of manganese. Process data is based on rough estimations; the overall data quality is very poor. |
| Start Date                   | 1994                                                                                                                                                                                                                                                                                                                          | 1994                                                                                                                                                                                                                                                                                                                                                                                                                                    | 2003                                                                                                                                                                                                                                                                                                                                                                                                                           |
