## 5.1 Exploitation of manganese ore

### 5.1.1 Production process

**Mining:** Manganese ores are usually mined in open pits. Adelhardt & Saiger (1999) reports an estimated share of 70% surface mining activities in the mine production in 1994. The deposits are of various nature and therefore the average manganese concentration differs greatly, from Asia with 24%<sub>wt</sub> to Australia with 48.5%<sub>wt</sub> and a world-wide average of 35.7%<sub>wt</sub> manganese content in the ore.

**Beneficiation:** After mining, the ore is first crushed in several stages with jaw and / or cone crushers, and then subsequently ground with rod and or ball mills and finally screened for classification. In a second step the classified material it is subjected to gravity concentration to separate the metal-bearing particles from the unwanted minerals. For this drum separators and de-watering screens for lumps are used and cone separators and a high-gradient magnetic separator for fine material. No flotation is done. Recovery of Manganese vary in a range from 65% to 75% (Adelhardt & Saiger (1999)). Various intermediate treatment processes can be applied to manganese natural ores or concentrates prior to smelting to a ferroalloy or direct addition to a steel making process. These processes are employed for one or both of the following two reasons: 1) to convert a fine ore to a more suitable size, and 2) to calcine and/or reduce the ore to a more suitable final product. Agglomeration processes include nodulizing, pelletizing, and briquetting. Reduction can be carried out in a rotary kiln or sinter plant. Sintering has become the preferred process for intermediate treatment (Wellbeloved et al. (1997)).

### 5.1.2 Emissions & Waste

#### Mining

The major emissions are due to mineral born pollutants in the effluents. Open cut mining generates large quantities of dust, which contains elevated contents of metals. Rain percolate through overburden and accounts to metal emissions to groundwater. Overburden is deposited close to the mine.

#### Beneficiation

Ore handling and processing produce large amounts of dust, containing PM<sub>10</sub> and several metals from the ore itself. Tailings are deposited as piles and in ponds. Since the tailings are not sulphidic, no acid rock drainage (ARD) occurs.

### 5.1.3 “Manganese, concentrate, at beneficiation” in ecoinvent

The module describes the production of manganese ore in 1994 for a world-wide production average. It is designed for the use of manganese ore as intermediary product in the production of ferromanganese, manganese metal and for the use of the ore in the manufacturing of batteries. Process data is taken mainly from Adelhardt & Saiger (1999), which conducted a material flow analysis for the consumption of manganese compounds in Germany.

The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.2 and Fig. 5.3. Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 11. The following paragraphs describe calculations, sources and assumptions chosen in this study.

#### Infrastructure and resource use

The mobile equipment used for exploration like drilling machines, scoop trams and underground trucks is inventoried with the diesel consumption, which is reported in Adelhardt & Saiger (1999). The

used module “diesel, burned in building machine” includes the infrastructure of these machines. Use of conveyor belt was assessed according Tab. 5.2.

The world average manganese content after beneficiation amounts to 42.4%, a yield from mining and beneficiation of 69.2% can be calculated (Adelhardt & Saiger (1999)).

According to part “Non Ferrous Metal Winning – Auxiliary Processes” no direct land use for underground mining (30%) is inventoried, land use for open pit mining (70%) is assessed with  $0.0025 \text{ m}^2/\text{t}$ , yielding a  $1.75 \cdot 10^{-3} \text{ m}^2/\text{t}$  and  $52.5 \cdot 10^{-3} \text{ m}^2/\text{t}$  respectively. A lifetime of 30 years is assumed. Mining facilities are inventoried as unspecific module according to part IX “Non Ferrous Metal Winning – Auxiliary Processes”.

**Tab. 5.2 Assumptions for infrastructure used in underground mining exploration. As lifetime ten years are estimated, and 5000 working hours yearly.**

| Action      | Share | Machine                     | Throughput   | Unit       | Infrastructure  |
|-------------|-------|-----------------------------|--------------|------------|-----------------|
|             |       |                             | t / lifetime | Length (m) | m / t ore mined |
| Open pit    | 70 %  | Conveyor belts (2000 t / h) | 100'000'000  | 10'000     | 1E-4            |
| Underground | 30%   | Conveyor belts (2000 t / h) | 100'000'000  | 2'000      | 2E-5            |
| Mix         |       |                             |              |            | 7.6E-5          |

## Mining

According to Adelhardt & Saiger (1999) 70 % of the manganese ore world production originates from surface mining operations. The overburden – 2.61 kg per kg ore concentrate extracted – is disposed in piles near the mine, the standard module for disposal of non-sulphidic overburden was chosen, which includes the land use and transformation through the disposal. Refilled overburden is assumed to be burden free. No overburden is refilled according to Adelhardt & Saiger (1999). In the world-wide average  $0.25 \text{ m}^3/\text{t}$  crude ore of the pit water is used for the beneficiation. The remaining pit water is not inventoried as output but its emissions are inventoried together with the emissions of the beneficiation step. The specific use of explosives vary between 0.1 kg (South America) and 0.3 kg (Africa) per tonne raw ore with a world-wide average of  $0.26 \text{ kg} / \text{t}$ . Diesel use ranges from 0.7 (South America) to 2,3 (Australia) with an average of 1.2 litre per tonne ore exploited. Electricity demand is comprised in beneficiation.

## Beneficiation

Once the ore is mined, it is ground and classified, no flotation occurs. The separated gangue is disposed on heaps, the concentrated ore is fed to the metallurgy, which is assumed to be on-site. The respective standard module “disposal, non-sulphidic tailings, off-site” is chosen. (s. “Non Ferrous Metal Winning – Auxiliary Processes”, chapter “Disposal of Tailings and Overburden”).

The infrastructure of beneficiation is included in mining infrastructure. Dust emissions comprise additionally the dust emissions due to mining activities. Hilbrans & Hinrichs (1999) assume for the nickel mining a share of 60% hydroelectricity due to the operations high and constant energy demand. The value comprises the electricity demand of the mining, which is expected to be small compared to the beneficiation.

**Steel:** The steel input (abrasion) for chromite milling is documented in IPPC (2002) for a single Finnish chromite mine (Kemi site) and amounts to  $300 \text{ g} / \text{t}$  ground ore. Since non information on steel consumption in the beneficiation of manganese ore is available and the beneficiation process works analogous to chromite winning, this value is also taken in this study. The mill (rods, balls, etc.) consists of special austenitic manganese steel of Hadfield grade, which is inventoried as chromium steel as a proxy.

**Water use & Effluents:** Water use for mining and beneficiation is documented in Adelhardt & Saiger (1999) and is inventoried in this study as originating from river without pumping activities. As no data on pit water use are given, the specific water use for chromite exploitation of  $1.5 \text{ m}^3 / \text{t}$  raw ore mined was chosen. The water input for beneficiation is given as  $0.8 \text{ m}^3 / \text{t}$  raw ore mined. As no data on emissions to water could be found, the recommendations of the world bank for base metal sites was used (Tab. 5.3). These recommended maximum concentrations are multiplied with the sum of effluent volumes from mining and beneficiation ( $3.5 \text{ m}^3/\text{t}$  ore). The value of  $150 \text{ mg} / \text{l}$  COD is assumed to amount to 150% of BOD (Zimmermann et al. (1996)). Values for TOC are calculated using the standard procedure in Frischknecht et al. (2003) approximating the unknown organic matter with the simplified formula for organic matter  $\text{C}_6\text{H}_{12}\text{O}_6$ . This gives  $58.7 \text{ mg} / \text{l}$  TOC and DOC respectively.

**Dust:** A case study in Anonymous (1998a) on a projected open cut gold-copper mining and processing facility in Australia predict annual dust emissions between  $0.18 \text{ kg/t}$  and  $0.46 \text{ kg/t}$  of dust produced per tonne of ore mined. The prediction was made using the Emission Estimation Technique Manual for Mining (NPI (2001)). The maximum value of  $0.46 \text{ kg/t}$  is chosen for total dust emissions, the value for underground mining is assessed with 80% of this amount. The dust composition is approximated with the manganese ore composition from Tab. 3.1 and the demands on quality for metallurgical grade ore. For  $\text{PM}_{10}$  values, the ratio TSP :  $\text{PM}_{10}$  :  $\text{PM}_{2.5}$  of manganese ore mining  $101.72 : 50 : 5 \text{ g} / \text{t}$  ore taken from the CEMIP-database<sup>1</sup>, i. e. one tonne emitted dust corresponds to  $492 \text{ kg PM}_{10}$  and  $49 \text{ kg PM}_{2.5}$  respectively. The airborne emissions resulting from mining and beneficiation activities are summed up in Tab. 5.4. In Ecoinvent, for particulates differential classes are used adding up to the total dust emission, i. e.  $49 \text{ kg PM}<2.5$ ,  $442 \text{ kg PM}_{2.5-10}$  and  $508 \text{ kg PM}>10$  per tonne of total dust.

### Data quality

Data for major mass fluxes are satisfactory, while the emissions to water and to air are based on assumption. The emissions to water may additionally be overestimated due to different system boundaries of reported effluent volume from Adelhardt & Saiger (1999) and recommendations in Anonymous (1998b). Furthermore, high uncertainties are associated with the chosen level of impurities of Pb, As, Cu and Zn in the manganese ore resulting in emissions to water and to air. The emissions from tailings and overburden are assessed in another module, which itself contains rough assumptions of a global overburden and tailings composition and a simplified disposal scenario. Emissions though can vary considerably from case to case.

Overall, the data quality is not satisfactory for this module. For specific purposes such as the use as battery grade ore in the battery manufacture further investigations concerning process specific emissions are necessary.

| <sup>a</sup> Metals, which are frequent impurities in manganese ore. Rough assumption.                                                                               |                |                   |
| <sup>b</sup> manganese ore is not sulphidic, therefore no use of this substance and consequently no emission is assumed.                                             |                |                   |
| <sup>c</sup> Maximum values relates to the whole range of base metal extraction. This specific emission is not assumed to be of importance in manganese extraction.. |                |                   |

**Tab. 5.4 Emissions to air resulting from mining activities per tonne mined ore. Values for total dust emission are taken from Anonymous (1998a), partition of fractions of particulate matter from the CEMIP-database (mining of manganese ore), the dust composition correspond to the average manganese ore from “3.1 Manganese ore” in this study. The impurities As, Pb, Cu and Zn are based on quality demands for metallurgical manganese ore: Mn  $\geq$  48%, Fe  $\leq$  6%, As  $\leq$  0.18%, Cu+Pb+Zn  $\leq$  0.3% (Adelhardt & Saiger (1999)), assuming single emission factors for Cu  $\leq$  0.1%, Pb  $\leq$  0.1%, Zn  $\leq$  0.1%.**

| <b>Emission to air</b> | <b>Unit</b> | <b>Emission per tonne mined ore</b> |

## 5.2 Winning of high carbon ferromanganese

Generally, high-carbon ferromanganese and silicomanganese are produced from a blend of manganese-containing ores, and in the case of silicomanganese, slag and silica are added. High-carbon ferromanganese can be converted to medium-carbon manganese by an oxygen blowing process, and silicomanganese can be further refined into medium- or low-carbon ferromanganese as well as manganese metal.

### 5.2.1 Production process and infrastructure

Ferromanganese can be produced in blast furnaces in a manner similar to pig iron and spiegeleisen; however, in the Western world only four producers employ this method. In the former Soviet Union, the majority of the high-carbon ferromanganese is produced in blast furnaces. The choice of the use of blast furnaces over electric furnaces is based on the relative price of coke and electricity. Blast furnaces are usually used where the cost of power is high in relation to coke. In blast furnaces, coke is used both as a reductant and as the energy source. The coke rate in blast furnaces is higher than in submerged arc furnaces, which use electricity as the power source. The product produced from blast furnaces generally contains 76 % Mn and 16 % Fe; the ferromanganese produced in the former Soviet Union is generally of a lower grade

According to Adelhardt & Saiger (1999), 15% (related to the manganese contained) of the manganese production was done by blast furnace and 75% by electric arc furnaces to produce silico- or ferromanganese, the rest being done mainly by electrolysis for other purposes.

The raw materials required for the production of high-carbon ferromanganese are manganese ores, fluxes such as limestone, dolomite, or silica, and solid fuels and reductants such as coke.

In order to produce ferromanganese of the required grade a single ore is seldom suitable because the desired Mn/Fe ratio of the charge determines the Mn content of the final product. Ores from various sources are therefore blended to achieve the ideal ratio and to limit the contents of the deleterious components silica, alumina (bauxite), and phosphorus in the raw material mix.

#### Blast furnace

In comparison to iron making, high gas temperatures are required in ferromanganese production because the reduction of manganese(II) oxide takes place at a higher temperature than is required for the reduction of wustite. This is achieved by oxygen enrichment of the hot blast. The recovery of manganese in the alloy is usually 75 – 85 %. This is influenced by the MnO content of the slag, the slag-to-metal ratio, and losses in the flue gases. The MnO content of the slag is highly dependent on the basicity ratio  $(\text{CaO} + \text{MgO})/\text{SiO}_2$ .

The reduction of the higher manganese oxides to manganese(II) oxide takes place in the upper zone of the shaft (reduction of manganese oxides with carbon monoxide and carbon). These generally occur below 900 °C and are indirect. The reactions are exothermic, and the heat generated causes high top temperatures and necessitates water cooling of the furnace top. The reduction of manganese(II) oxide  $\text{MnO} + \text{C} \rightarrow \text{Mn} + \text{CO}$  is highly endothermic, in contrast to the weakly endothermic reduction of wustite. This requires higher temperatures and, consequently, higher coke rates are required for the smelting of ferromanganese in blast furnaces.

#### Electric arc furnaces

The majority of producers of ferromanganese in the Western world use submerged arc electric furnaces. Although electric furnaces have lower capacities than blast furnaces they have the advantage that the heat requirement is provided by electricity, and coke and coal are added to the feed only as reductants. Recently built electric furnaces have capacities of 75 – 90 MVA. Smaller furnaces are still popular with producers because they offer flexibility in that they can be switched more easily between different products than their larger counterparts. Electric furnaces used are generally circular and have

three electrodes. The reduction of manganese(II) oxide occurs by the contact of carbon with the molten oxide in the slag phase. The overall reaction is :

Large electric furnaces are usually completely closed at the top, and the CO-rich gas leaves the furnace at approximately 290 °C and is cleaned in cyclones and venturi scrubbers. The gas is then either flamed off to the atmosphere or, more recently, is used to generate electricity. Smaller furnaces may be open, the gas then is usually withdrawn by fans and cleaned in a bag-filter plant. In this case the gases are completely burnt in the furnace and have no commercial value.

After the metal is tapped from the furnace it is cast into moulds formed from ferromanganese fines or cast iron and allowed to solidify. The alloy is then removed, crushed, and screened into various size fractions, depending on the requirements of the user. An alternative to this practice is the use of a casting machine. In this case the metal is tapped directly onto a moving train consisting of small molds. The metal then solidifies and is ejected from the mould at the end of the strand.

Adelhardt & Saiger (1999) distinguishes between a electric arc furnace process with calcareous flux and one without flux, where the energy consumption is smaller due to reduction of the ore by excess CO. The yield of the process without flux is smaller with 70% compared with 75% of the process with calcareous flux, due to a slag richer in MnO. However, the manganese rich slag – sometimes over 25% manganese – of the process without flux is used in the production of silicomanganese, enhancing the overall yield considerably.

### **Silicomanganese**

The production of silicomanganese is very similar to the ferromanganese production. The main difference is in the type of flux – silica instead of lime – and of course the composition of the product. Also the energy demand is some what higher than in the production of ferromanganese. Many plants produce alternately ferrosilicomanganese and then – processing the developed slag – silicomanganese. However, for purposes of inventorying silicomanganese it is suitable to take ferromanganese as proxy.

## **5.2.2 Emission**

**Air:** The main environmental impact by producing ferro-alloys is the emission of dust and fume from the smelting processes. Dust emissions occur as well from storage, handling and the pre-treatment of raw materials where fugitive dust emissions play an important role. Depending on the raw material and the process used other emissions to air are SO<sub>2</sub>, NO<sub>x</sub>, CO-gas, CO<sub>2</sub>, polycyclic aromatic hydrocarbon (PAH), VOCs, and volatile metals. The formation of dioxins in the combustion zone and in the cooling part of the off-gas treatment system (de-novo synthesis) may be possible.

**Water:** Water emissions are produced from cooling, granulation and other processes and site related effluents. The wastewater generated by a wet cleaning abatement system plays also an important role.

## **5.2.3 Waste**

Process residues and by-products with a significant amount is slag, filter dust and sludge and spent refractories. These materials are already recycled and reused to a large extent where it is possible. Rich slag, that means slag with a relatively high proportion of metal oxides, is used as raw material in other ferro-alloy productions.

### 5.2.4 Ferromanganese in ecoinvent

This part is mainly based on Adelhardt & Saiger (1999). General process description was taken from Wellbeloved et al. (1997), process specific emissions from IPPC (2001), IPCC (1996), EPA (1998) and EC (2002).

Adelhardt & Saiger (1999) differentiates between a blast furnace process (15% of the production respective to manganese contained) and the two processes with electric arc furnaces (with calcareous flux and without flux, total of 60% of the production) and finally the production of silicomanganese in electric arc furnaces (13%), totalling to 88% of the total manganese processed to high-carbon ferromanganese. In this study an aggregated mix is used, which represent an average production of ferromanganese and silicomanganese. 2% is processed to low-carbon ferromanganese, while 10% is used in the non-ferrous metallurgy, the chemical industry and the battery manufacture (Fig. 5.1). It is suitable also for the production of silicomanganese, which is produced in a similar way, although using silica instead of lime and about 10% more energy respective to the manganese contained (Tab. 5.5).

The module describes the world average consumption mix for ferromanganese in Europe in 1994. The situation for Germany described in Adelhardt & Saiger (1999) is taken as proxy for Europe. It is designed for the use of the metal as alloying element. The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 5.4 (inputs) and Fig. 5.5 (output). Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 11. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one kg of ferromanganese with an average manganese content of 74.5%.

**Infrastructure and transport:** The production infrastructure is represented by the non-ferrous metal smeltery that is describes in part “Non ferrous metal winning, auxiliary processes” of this report. It is assumed that the raw materials manganese ore, silica, dolomite, lime, coke and the disposals slag and cake are transported by lorry over 50 km.

**Energy, raw-materials and output:** A weighted average of the different inventoried processes – blast furnace and electric arc furnace- is calculated. An overview over different in- and output values from different sources is given in Tab. 5.5. Slag is assumed to be sold to silicomanganese production, dust as reported in Adelhardt & Saiger (1999) is assumed to build process residue, which has to be disposed into a landfill. This is inventoried in this study with the disposal of non-ferrous slag as proxy.

**Emissions to air:** Air emissions are taken from various sources, they are summarised and discussed in Tab. 5.6.

**Water use and emissions:** Water use for European ferrochrome production is reported in IPPC (2001), the average of 20 m<sup>3</sup> (10 m<sup>3</sup> – 30 m<sup>3</sup>) per tonne is chosen as an approximation, resulting in 10 m<sup>3</sup> of effluents (volume of process water). The effluent has to be treated in a communal waste-water treatment plant, a process which is inventoried separately in the chosen module “treatment, sewage, unpolluted, to wastewater treatment, class 3”. Emissions to water are inventoried separately each as entry according to reported values of effluents after internal process water treatment and before waste water treatment plant (Tab. 5.7).

**Production and import to Europe.** As proxy for the consumption pattern the imports to Germany in 1995 are chosen (Tab. 5.8). Only the ferromanganese imports were considered, assuming, that the imported manganese ore is destined mainly to the chemical industry and the battery manufacture and only a small amount is used for blending in the domestic ferromanganese production. This results in a transport intensity of 16 tkm ship and 2 tkm freight train per kg ferromanganese (Tab. 5.9).

### Data quality

Process data is satisfactory and valid for the whole world-wide primary ferromanganese production. Process specific emissions to air and water had to be taken from an other source, which cover other

geography and technology. Nevertheless the overall quality of the module is fair. The import pattern may have changed in the recent years with a trend to longer import distances.

**Tab. 5.5 Production of ferromanganese and silicomanganese. In- and outputs for the production of ferromanganese with different processes. The last two columns relate to the production of 1 kg manganese alloy using a weighted mix for ferromanganese according to the share in global production. (Adelhardt & Saiger (1999))**  
Data for silicomanganese show, that the production of ferromanganese is suitable as a proxy inventory.

| Inventory                                                                                                                                                                                                                                                                                                                                                                                                                                                        | Unit           | Ferromanganese    |                      |            | Silico-manganese     | Ferromanganese <sup>e)</sup> | Silico-manganese |

<sup>b)</sup> Bag house  
<sup>c)</sup> Average of EPA values are chosen for world wide mix.  
<sup>d)</sup> SNAP-Code 040309, „Other - Installations for smelting and casting of non ferrous metals“  
<sup>e)</sup> Value taken from ferrosilicon production  
<sup>f)</sup> values for Electric arc furnace (low) and blast furnace (high) resulting in a weighted average value (see Tab. 5.5)  
 CO<sub>2</sub> emission is not inventoried separately as it is included in the emissions of the "hard coal, burned..." inputs

**Tab. 5.7 Emissions to water in the production of 1 tonne ferromanganese. The values are reported values for ferro-chromium production (IPPC (2001)) chosen as approximation. Emissions are before final waste-water treatment and after internal abatement including lamella thickener, vacuum filter and a sand and carbon filter. Based on the chosen values, final emissions into water are calculated.**

| Emission to Water<br>(before treatment)  | Unit   | IPPC (2001) |      | This Study        | Resulting values after treatment |
|------------------------------------------|--------|-------------|------|-------------------|----------------------------------|
|                                          |        | Low         | High |                   |                                  |
| TSS                                      | kg / t | 5           | 10   | 7.5 <sup>a)</sup> | 0.375                            |
| PAH                                      | mg / t | 300         | 1000 | 650 <sup>b)</sup> | 65                               |
| waste from internal wastewater treatment |        |             |      |                   |                                  |
| dry cake                                 | kg / t | 200         | 400  | 300 <sup>c)</sup> | 300                              |

<sup>a)</sup> An elimination of 95% TSS assumed, resulting in an emission after treatment of 375 g TSS / t  
<sup>b)</sup> Based on Zimmermann et al. (1996) transfer coefficients of 10% to water is assumed, resulting in emissions of 65 mg PAH / t. Resulting emissions to air due to metabolism as CO<sub>2</sub> and NM VOC are neglected.  
<sup>c)</sup> Dry cake results from internal waste-water treatment. In this study it is assumed to be disposed as inert waste to an inert material landfill.

### 5.3 Production of metallic manganese

Manganese metal is mainly used in the iron, steel and aluminium industry. In aluminium production for instance manganese is used as an alloying element improving the product hardness. For the production of pure manganese metal several processes are known (Wellbeloved et al. (1997), IPPC (2001)):

- Electrolysis of aqueous manganese salts
- Electrothermal decomposition of manganese ores
- Silico-thermic reduction of manganese ores or slag
- Alumino-thermic reduction of manganese ores or slag
- Distillation of ferro-manganese
- Electrolysis of fused salts

From the above listed processes the first two are the most important ones. The other processes are not economically significant.

**Electrolysis of aqueous manganese salts:** The production of manganese metal by the electrolysis of aqueous manganese salts requires at first a milling of the manganese ore. Milling increases the active surface and ensures sufficient reactivity in both the reduction and the subsequent leaching steps. After milling the manganese ore is fed to a rotary kiln where the reduction and calcination takes place. This process is carried out at about 850 - 1000 °C in a reducing atmosphere. As a reducing agent, several carbon sources can be used e.g. anthracite, coal, charcoal and hydrocarbon oil or natural gas. The calcined ore needs to be cooled below 100 °C to avoid a further re-oxidation. The subsequent leaching process is carried out with recycled electrolyte, mainly sulphuric acid. After leaching and filtration the iron content is removed from the solution by oxidative precipitation and the nickel and cobalt are removed by sulphide precipitation. The purified electrolyte is then treated with SO<sub>2</sub> in order to ensure plating of γ-Mn during electrolysis. Electrolysis is carried out in diaphragm cells. The cathode is normally made of stainless steel or titanium. For the anode lead-calcium or lead-silver alloy can be used. After an appropriate reaction time the cathodes are removed from the electrolysis bath. The manganese that is deposited on the cathode starter-sheet is stripped off mechanically and then washed and dried. The metal is crushed to produce metal flakes or powder or granulated, depending on the end use.

**Electrothermal decomposition of manganese ores:** The electrothermal process is the second important process to produce manganese metal in an industrial scale. The electrothermal process takes place as a multistage process. In the first stage manganese ore is smelted with only a small amount of reductant in order to reduce mostly the iron oxide. This produces a low-grade ferro-manganese and a slag that is rich in Mn-oxide. The slag is then smelted in the second stage with silicon to produce silico-manganese. The molten silicomanganese can be treated with liquid slag from the first stage to obtain relatively pure manganese metal. For the last step a ladle or shaking ladle can be used. The manganese metal produced by the electrothermal process contains up to 98% of Mn.

#### 5.3.1 Emissions & Wastes

The general manufacturing of refractory metals normally takes place at high temperatures. The environmental impact on air, water and land can be classified as follows.

**Emissions to air:** Dust and fume emissions from smelting, hard metal and carbide production; Other emissions to air are ammonia (NH<sub>3</sub>), acid fume (HCl), hydrogen fluoride (HF), VOC and heavy metals.

**Emissions to water:** Overflow water from wet scrubbing systems; Wastewater from slag and metal granulation; Blow down from cooling water cycles.

**Wastes:** Dust, fume and sludge; Slag.

### 5.3.2 “manganese, pure metal, at regional storage” in ecoinvent

The module describes the manganese metal consumed in Europe in 1994. It is designed solely for the use of the metal in special applications like sputtering or alloying element. This module is explicitly not to be used as alloying element in bulk iron or steel industry. The overall quality of this module is poor due to a lack of data.

The layout of the module with general flow information, remarks, sources, values and uncertainty information is shown in Fig. 5.6. Ecoinvent meta information for this process are summarised in Tab. 5.1 on page 11. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one tonne of manganese consumed in Europe. No information is available on the share of the two major production processes, a ratio electrothermal/electrolysis of 75/25 is assumed.

#### **Electrolytic process**

No information on material input and output were available. The energy demand is stated in Wellbeloved et al. (1997) to be 9 - 12 kWh per kg manganese. Considerable amounts of chemicals ought to be used for reduction and leaching, but no detailed information is available. Hence none of these emissions are taken in account. For grinding prior to electrolysis, a value of 20 kWh electrical energy per tonne processed ore is assumed, reported in IPPC (2002) for base metal sites. A yield of 60 % is roughly estimated.

#### **Electrothermal process**

The production of bulk manganese by this method is a well protected secret and little information appears in the literature. The process is a refinement of the silicothermic reduction of manganese. It resembles that of low-carbon ferromanganese in electric arc furnaces of 1 – 3 MW power consumption. The raw material used is either low-iron manganese ore or a manganese slag concentrate. The silicon is in the form of a special silicomanganese which is made from a manganese slag concentrate or from pure ores. Reduction as complete as possible is ensured by the addition of lime, which forms a basic slag (Wellbeloved et al. (1997)).

In this study it is assumed, that 75 % of the Mn contained in the raw material originates from ore with a special grade, which is processed in a way similar to high-coal ferromanganese, the rest being slag, which is burden free. No information on the further refining process of manganese is available and no estimations are made in this study. Adelhardt & Saiger (1999) reports efficiencies between 60 % and 65 %, for this study the average of 62.5% was chosen.

**Import to Europe:** Since some transport intensity is already included in the 1.2 kg ferromanganese used for the electrothermic process, no further transportation is inventoried within this module. This approach is obviously not correct, but it will not influence the data quality of the inventoried process, which is already poor.

#### **Data quality**

This process is mainly based on rough estimates. The process specific emissions could be considerable but due to lack of data none are considered. This module only is to be used, where it plays a minor role, like in sputtering. If the impact of the modules use is considered to be high, more specific investigations have to be conducted.

## Comments on this part

The production of lead, zinc, cadmium and indium is inventoried in the modules described in this report. Data reported are mainly based on literature and theoretical models.

The Swiss Federal Office for the Environment (FOEN) commissioned Empa in 2005 to identify the datasets that have to be improved in order to improve the overall quality and applicability of metals inventories in the metal processing and electronic industry. Based on that preparatory study the significance of the metals extracted from combined lead and zinc ores was identified. In order to improve and extend datasets the original parts have been reworked completely for ecoinvent version 2.0. It has been extended by a series of metals that are mainly produced from intermediate raw materials originating from lead-zinc extraction: cadmium, silver and indium.

This part corresponds to the original report in Althaus et al. (2004) on lead and zinc. The inventory modelling has been done consistently with multi output modules using economic allocation. All the errors reported in previous versions 1.x as documented in Frischknecht et al. (2006) have been corrected. Notably the emission factors to air for primary zinc production have been corrected and updated with the revised source (EEA, 2003). Likewise the values in Tab. 6.19 have been corrected as reported in the changes to v1.1.

Chapter “6 Cumulative Results and Interpretation” of the original report has been deleted for the current update.

**Oxide Ores**

**Sulfide and Oxide Ores**

**Sulfide Ores**

**Interconnected Carrier Metal Cycles**

**Legend:**

- Carrier metals, bulk metals, generally of lower value.
- Co-elements that also have considerable production infrastructure. Valuable to high economic value; some used in high-tech applications.
- Co-elements that have no, or limited considerable production infrastructure. Mostly highly valuable, high-tech metals (e.g., essential in electronics).
- Co-elements that end up in residues, or as emissions. Costly because of waste management or end-of-pipe measures.

## 2 Reserves and Resources of Materials

### 2.1 Lead

Lead, like copper and zinc, is a markedly chalcophilic element. Its mean abundance in the Earth's crust is 16 g/t (0.0016 %). Enrichments occur only in the pneumatolytic and especially the hydrothermal sulphide phase in the form of vein (lode), impregnated, and particularly metasomatic deposits. Sedimentary enrichments are of little importance.

Galena or lead sulphide [CAS 1314-87-0], PbS, theoretically 86.6 % Pb, is by far the most important lead mineral and the sole primary one. Other common forms of naturally occurring lead are usually associated with or derived from galena deposits. Frequent impurities in lead minerals are zinc, copper, arsenic, tin, antimony, silver, gold, and bismuth. Of the total world lead and zinc mining output, mixed lead-zinc ore deposits are the most important and account for ca. 70 % of the total production of both metals. In second place are deposits that contain predominantly lead ores (ca. 20% of total production), and the remainder (ca. 10%) is obtained as a by-product from zinc, copper – zinc, and other deposits (Sutherland et al., 1997). For sulphidic deposits of the zinc-lead-copper type Krauss et al. (1999) reports an average composition in parts of metal by the mass of 2.4 Zn : 1.4 Pb : 1 Cu. Mined lead ores contain approximately 6 % Pb in average (Ayres et al., 2002).

**Tab. 2.1** Mine production and reserves of lead in 2005. “Reserves” is referred to as “the part of the reserve base which could be economically extracted or produced at the time of determination”, while “Reserve base” denotes “that part of an identified resource that meets specified minimum (...) criteria related to current mining and production practices” (USGS, 2006b).

| Lead                     | Mine production  |                                 | Reserves | Reserve base |

## 2.2 Lead as secondary resource

Recycling of lead is performed at a high level world wide (USGS, 2006b). The production of secondary lead, for example in the US, has risen from about 23'131 tonnes in 1907<sup>1</sup> (USGS, 2006c) to 1'100'000 tonnes in 2005 (Gabby, 2006.) At present it is estimated that about 85.0% lead used can economical be recovered (Thornton et al., 2001). Because of the permanently increasing demand (demand is higher than lead is available), the price of lead raised comparably (as general tendency for large price fluctuations can also be observed in Fig. 1).

Fig. 2.1 Value of lead (adopted from DiFrancesco et al., 2006).

On a global level, the refining of secondary lead has increased from ~ 1'500'000 tons in 1976 to approximately 2'800'000 tons in 1998 (Dzioubinski & Chipman, 1999). Key source for secondary lead are lead-acid batteries contributing with 92.0% to the total secondary lead production of the US (Gabby (2004)). The treatment of such batteries is enforced by adequate governmental directives, for instance in France (100.0%), Denmark (99.9%) and Portugal (75.0%) (Thornton et al., 2001). Beside automotive batteries, secondary lead is recovered from used lead-acid rechargeable batteries as for instance applied for back-up power supply in antenna stations of mobile phone networks (Scharnhorst, 2005).

In recent years, the primary production has seen a shift from pure primary production to more flexible technologies that are able to treat increasingly also secondary materials (QSL furnace at Stolberg facility, Kivcet furnace at Trail). Hence, the distinction between processing primary and secondary lead is more and more blurred. The UK based consultancy CHR Metals estimate that the amount of secondary lead production has raised to 58% of the world lead supply (Roberts, 2003). The ILZSG-statistics indicate a further decrease in the share of primary (mine) production compared to the total reported metal production, viz. an increase in secondary (post consumer) production (Tab. 2.2).

<sup>1</sup> The earliest documented statistics on secondary lead.

Tab. 2.2 Lead production and consumption worldwide. Statistics taken from ILZSG (2007) and USGS (2006b).

|                | Mine Production     | Metal Production | Metal Consumption | Ratio mine production / metal production |
|----------------|---------------------|------------------|-------------------|------------------------------------------|

## 2.3 Zinc

With an average concentration in the earth's crust of 65 g/t (0.0065 %), zinc is the 24th element in order of abundance. It occurs only in the chemically combined state. Like copper and lead, zinc is a strongly chalcophilic element. It usually occurs as sulphide, mostly deposited from hydrothermal solutions and simic and sialic magmas. Sedimentary deposits are of less importance.

By far the most important zinc mineral today, and probably also the only primary ore, is zinc blende. The other minerals listed here are of only local importance. Native zinc is practically nonexistent. Isomorphous components of zinc blende such as cadmium, gallium, germanium, indium, and thallium do not form deposits of their own. Some of these metals are recovered during zinc ore processing.

Zinc blende (or sphalerite, ZnS) has the theoretical composition 67.09 % Zn, 32.91 % S. It is light yellow to black in colour, usually black to brown depending on the iron content, crystallises in the regular tetrahedral system, and has a Mohs hardness of 3 – 4 and a density of 3.9 – 4.1 g/cm<sup>3</sup>. The most important impurity is FeS, which is always present at concentrations between 0.3 and >20 %. Sulphides of Pb, Cd, Mn, and Cu are often present. Zinc blende also often contains small amounts of As, Sn, Bi, Co, Hg, In, Tl, Ga, and Ge, and nearly always contains Ag and often Au. The hexagonal modification of Zinc blende is known as Wurzite (conchoidal or radiating blende). Its density is 3.98 g/cm<sup>3</sup>. Other less important minerals are: Smithsonite (zinc spar, calamine) ZnCO<sub>3</sub>; Hemimorphite, Zn<sub>2</sub>SiO<sub>4</sub> · H<sub>2</sub>O; Willemite, Zn<sub>2</sub>SiO<sub>4</sub>; Franklinite, (Zn,Fe,Mn)O · (Fe<sub>2</sub>,Mn<sub>2</sub>)O<sub>3</sub>, zinc bloom (hydrozincite), ZnCO<sub>3</sub> · n Zn(OH)<sub>2</sub>; red zinc ore (zincite), ZnO; and troostite (bainite), (Zn,Mn)<sub>2</sub>SiO<sub>4</sub> (Graf & Schleining, 1997).

According to Ayres et al. (2002), the average concentration of the material currently mined is 3-11%. The annual mine production and world-wide reserves are listed in Tab. 2.3.

Approximately 30% of the yearly zinc consumption in Europe is secondary or recycled zinc. Approximately 50% of this secondary zinc is recycled within the industry. This is particularly true in the galvanising and brass sector. Scrap arising from the production or processing of products can be recycled almost immediately. Residues and scrap, which are relevant and significant to the secondary zinc industry, include dust from copper alloy making, residues from the die casting industry, ashes, bottom and top drosses from the galvanising industry, old roofing and other sheet materials, non-ferrous fraction from the shredding of old cars and of other mainly steel containing products, dust from electric arc steel making and cast iron making and residues from chemical uses of zinc and burnt tyres (IPPC, 2001).

**Tab. 2.3** Mine production and reserves of zinc in 2006. “Reserves” is referred to as “the part of the reserve base which could be economically extracted or produced at the time of determination”, while “Reserve base” denotes “that part of an identified resource that meets specified minimum (...) criteria related to current mining and production practices” (USGS, 2006b).

| Zinc                     | Mine production  |                                 | Reserves | Reserve base |

## 2.4 Cadmium

Cadmium is widely distributed. It occurs in the earth's crust with a content estimated to be between 0.08 and 0.5 ppm. In top soil cadmium content usually lies between 0.1 and 1 ppm. None of known cadmium minerals such as cadmium sulfide (greenockite, 77.6 % Cd), cadmium carbonate (61.5 % Cd) and cadmium oxide (87.5 % Cd) is of industrial importance because the deposits are too small. Only zinc minerals in which cadmium is found as an isomorphic component, with concentrations ranging from 0.05 to 0.8 %, averaging about 0.2 % have economic significance for cadmium recovery. In addition, lead and copper ores contain small amounts of cadmium, which can be separated during the roasting and smelting processes (Schulte-Schrepping & Piscator, 2002).

The bulk of the cadmium being recovered is associated with ores of sphalerite (ZnS) that is extracted for its zinc content. Cadmium therefore is a by-product from the zinc extraction where it accumulates in flue dust (pyrometallurgical processes) and purification precipitates (hydrometallurgical processes). Estimated world resources of cadmium were about 6 million tons in 2006, based on identified zinc resources of 1.9 billion tons containing about 0.3% cadmium (USGS, 2007).

The recycling of cadmium is still on a low level. It basically occurs via the recovery of EAF dusts from zinc manufacturing. Hawkins et al. (2006) estimate that in the U.S. less than 20% of the cadmium in the product waste stream is currently collected for recycling. On a world wide average this number appears to be lower, a level of 10% seems to be a reasonable assumption.

This consideration, together with the assertion that 80% of the primary cadmium produced originates from zinc extraction (USGS, 2007) and under the assumption of stable stocks, leads to the estimate that 72% (=80% primary from zinc \* 90% primary in supply) of the cadmium supply may be related to the primary zinc production.

## 2.5 Indium

Indium does not occur as pure metal. Although widely distributed, it generally occurs in low concentrations. The content of indium in the earth crust is estimated to be 0.1 ppm. Indium is found as a trace element in many minerals and is accumulated during the extraction of the main metal values such as zinc, lead and copper.

### 2.5.1 Primary sources: Indium ores

Sphalerite is the most important indium-containing mineral followed by lead and copper sulfides. The amount of indium in sphalerite may vary widely even within a deposit. The indium concentration is typically 10 – 20 ppm, but may be as high as 1 % (Felix, 1996). An overview over different deposit types and ore grade / tonnage relationship is given in Fig. 2.2.

Due to its low concentrations indium is not mined for itself but is recovered as an important by-product of zinc metal processing operations. It accumulates during extraction in various intermediate products and waste. Due to the complex technology required to recover indium, only a few operations are able to produce the metal. The main producers of indium (Umicore, Dowa Mining, Nippon Mining, Sumitomo Metal Mining, Teck Cominco, Falconbridge) are all into zinc processing. However, Schwarz-Schampera & Herzig (2002) stress that the resource base is underestimated when only looking at zinc bearing minerals, since noteworthy deposits combined with tin (cassiterite) exist.

Fig. 2.2 Distribution of ore grade and reserve for different indium bearing deposits (Schwarz-Schampera & Herzig, 2002).

### 2.5.2 Secondary sources

Worldwide only small amounts of Indium (mainly Indium Tin Oxide (ITO) scrap) are recycled. The reason for the low recycling rate is the lack of infrastructure for collecting indium-containing products, although recycling is supposed to expand significantly if the current price of indium is sustained. Indium tin oxide (ITO) use is highly inefficient, as only about 15% of ITO is utilised in the LCD production process; the rest is scrap. The major problem in recycling the ITO scrap is the high cost associated with the process. The process takes about 12 weeks from collection of scrap to fabrication of secondary indium products. A large increase in ITO scrap could be difficult for the recycling industry to handle because of large capital costs, environmental restrictions, and storage space (USGS, 2006a).

Taking an average concentration of 2 ppm of ITO in collected backlights<sup>2</sup>, 90% recovery rate and 95% reprocessing efficiency, the required amount of scrap backlights to gain a kg indium would amount to 585 tonnes. Even with prices as high as 1'000 \$ per kg ITO a global collection system is not probable to evolve, and therefore no post consumer scrap recycling may be considered.

<sup>2</sup> Content in 17" backlight (1.8 kg) 1.76 ppm, in 15" backlight (1.1 kg) 2.05 ppm for total film thickness of 500 nm.

### 2.5.3 Indium Supply

The supply of indium mainly depends on a few zinc extracting operations in Canada, Russia, China and Japan (Stevens, 2007). Due to a sharp rise in ITO demand in LCD fabs the primary producer may not meet the demand. This development led to a dramatic increase of the price starting in 2003 (Fig. 2.3). The supply gap is filled with releases of strategic stocks and the processing of new scrap. In 2004 Teckcominco (2005) estimated that almost 50% of the supply was met by secondary (industry scrap) sources (Fig. 2.4). Stevens (2007) estimates that existing potentials for future indium supply (“x-factors”) may be activated by enhancing the recovery efficiency by 5%, treatment of secondary materials and a slowing down of the demand by LCD fabs. He estimates a share in reclaimed secondary (prompt scrap) sources of 60% in 2008 (Fig. 2.5).

Fig. 2.3 Indium prices with comments (Teckcominco, 2005; Metal Bulletin, 2006).

Fig. 2.4 Supply of Indium in 2004. Recycling of prompt scrap (ITO targets and the like) plays a vital role in the indium supply (Teckcominco, 2005).

| indium (metric tons) |                | 2004 | 2005 | 2006 | 2007 | 2008 |

Fig. 2.5 Estimated sources of Indium. Assumption that all potentials for indium recovery are seized and that the demand will slow down (Stevens, 2007). FPD = Flat panel display, CAGR = compound annual growth rate.

### 3 Coupled Production

The metals lead, zinc, cadmium, silver (contained in the parkes process crust of primary lead production) and indium are mainly found coupled in deposits. A compilation of world production is given in Tab. 3.1.

Namely the cadmium metal is almost exclusively from Zinc ores. Today approximately 80% of world cadmium production (=90% of the supply) was derived from mining, smelting, and refining of zinc, and the remaining 20% came from copper and lead smelting and the recycling of cadmium products (USGS, 2007). The ratio between the world mine production of Cadmium and Zinc is quite stable over the last 20 years at about 2 kg Cd produced per tonne extracted Zinc. This corresponds to the average concentration of Cd found in worked Zn ores of about 0.3%.

**Tab. 3.1 World production in metric tonnes per year compiled from Kelly & Matos (2007) through 2004, for 2005 and 2006 the respective mineral commodity summaries from USGS (2006b) were taken.**

## 4 Characterisation of the materials

### 4.1 Lead

The element lead (Pb, CAS 7439-92-1) is a lustrous metal. When freshly cut, surfaces are bluish white but oxidise readily to the familiar dull grey colour. Lead has four naturally occurring isotopes:  $^{208}\text{Pb}$  (51 – 53 %),  $^{206}\text{Pb}$  (23.5 – 27 %),  $^{207}\text{Pb}$  (20.5 – 23 %) and  $^{204}\text{Pb}$  (1.35 – 1.5 %). Three of the natural isotopes are radioactive ( $^{208}\text{Pb}$ , end product of thorium decay;  $^{206}\text{Pb}$  and  $^{207}\text{Pb}$ , from uranium series). A number of unstable radioactive isotopes of Pb also exist. Lead is a preferred shielding material against gamma rays and X-rays; if sufficiently pure, it does not become radioactive when used for shielding against neutron sources (Sutherland et al., 1997). Some physical properties are listed in Tab. 4.1.

Tab. 4.1 Some physical properties of lead (Sutherland et al., 1997).

| Physical properties of lead                                    |         |
|----------------------------------------------------------------|---------|
| Melting point °C                                               | 327.4   |
| Latent heat of fusion, J/g                                     | 23.4    |
| Boiling point °C                                               | 1741    |
| Latent heat of vaporisation, J/g                               | 862     |
| Vapour pressure, kPa 980 °C                                    | 0.133   |
| Density, g/cm <sup>3</sup> 20 °C                               | 11.336  |
| Mean specific heat, J g <sup>-1</sup> K <sup>-1</sup> 0–100 °C | 0.131   |
| Specific electrical resistance, Ω/cm 20 °C                     | 20.65   |
| Brinell hardness (20 °C)                                       | 2.5–3.0 |

### 4.2 Zinc

The remarkably low boiling point of 906 °C is important in pyrometallurgical zinc production processes. Zinc can be worked at temperatures as low as 120 °C, and its good deformability is the basis for some of its uses. Zinc is resistant to air because of the self-protective coating formed. It is also resistant to halogens, but is rapidly corroded by HCl gas. Because of its high surface area, zinc dust is much more reactive and can even be pyrophoric, e.g., reacting vigorously at elevated temperatures with the elements oxygen, chlorine, and sulphur (Graf & Schleining, 1997). Zinc is traded in different purity grades, which are specified by different authorities. In Northern America, SHG is the highest purity zinc grade, followed by HG and finally PW. Comparable specifications for primary zinc grades can be found in Europe (European Standard EN 1179, Tab. 4.2), in Japan (Japanese Industrial Standard JIS H 2107), and in Australia (Australian Standard AS 1242).

Tab. 4.2 Composition of different zinc grades in Europe, data provided by IZA<sup>3</sup>.

| EN 1179 Grade Designation | Pb    | Fe    | Cd    | Al    | Cu    | Sn | Total non-zinc | Zinc, min |

## 4.4 Indium

Indium is a very soft, silvery-white metal that has a bright luster. As a pure metal indium emits a high-pitched "cry" when it is bent. Both gallium and indium are able to wet glass. Indium has a low melting point (429.75 K) but a high boiling point (2353.15 K). Indium becomes superconducting at 3.37 K. Metallic indium is not oxidized by air or oxygen at room temperature. It reacts directly with arsenic, antimony, the halogens, oxygen, phosphorus, sulfur, selenium, and tellurium when heated. Indium dissolves only slowly in cold dilute mineral acids, but more readily in hot dilute or concentrated acids. Alkalis do not attack the massive metal. Indium forms alloys with most other metals. Extensive solid solutions are formed with lead, thallium, and mercury. Some properties of indium are compiled in Tab. 4.5 (Wikipedia Contributors, 2007; Felix, 1996).

Tab. 4.5 Some properties of the element indium (Wikipedia Contributors, 2007; Felix, 1996).

| Properties                                             | Unit                                              | Value                                                 |

## 5 Use / Application of Material

### 5.1 Lead

Generally toxicity concerns and substitution by plastics and copper have reduced the market considerably. Main applications of lead are the following (Sutherland et al., 1997):

**Batteries:** The battery market is by far the largest end use of lead. Batteries for starting, lighting and ignition (SLI) represent the predominant use of lead. Traction batteries are used to power electric vehicles. Stationary batteries are used for standby and emergency power supply.

**Pigments and Lead Compounds:** After batteries, the next largest use of refined lead is in glass making, ceramic glazes, plastic stabilisers, and paints. The lead pigment market is now very small.

**Semi finished Products:** Rolled and extruded lead, mainly sheet and pipe, account for about 8 % of total lead use.

**Cable Sheathing:** A major area of lead use was in the protection of electrical and telecommunications cables, but this market has declined drastically due to substitution by aluminium and plastics.

**Lead Alloys:** Solders, type metal, bearing alloys containing lead still account for about 4 % of the lead consumption.

**Gasoline Additives:** In 1972 the use of tetraethyl lead for improving the octane rating of gasoline was nearly 400'000 t/a. Since then, this sector has declined by 70 % due to restrictions through environmental legislation.

**Shot and Ammunition:** Shot and ammunition account for about 2 % of lead consumption and represent a steady market.

**Miscellaneous:** Uses that do not fall into the above categories account for about 4 % of lead use, and include products featuring the high density of lead such as wheel weights, yacht keels, ornamental items, stained glass, and massive radiation shielding.

Fig. 5.1 Applications of lead in 2001 (LME website<sup>5</sup>)

## 5.2 Zinc

Due to its manifold properties, Zinc is used in a broad field of applications (Tab. 5.1). The quantities of first- and end-use are given in Fig. 5.2. Main uses are as follows (Graf & Schleining, 1997):

In the industrialised countries, almost 50 % of the zinc consumed is used for corrosion protection. Commercial zinc (98.5 – 99.5 %) is usually used for hot-dip galvanising in production and jobbing plants, and high-purity zinc (99.95 %) for the continuous galvanising of steel strip or wire. The metallurgical processes used to produce the less pure grades of zinc means that lead is the main impurity present. This is an advantage, as the presence of 1 % lead reduces the surface tension of zinc by ca. 40 % compared with that of the high-grade product. The components being galvanised are therefore more effectively wetted by the molten zinc.

Pressure die casting is another major area of use and is dominated by alloys of the type ZnAl4Cu1 and modifications thereof. Approximately 50 % of all zinc pressure die castings go to the automobile industry.

Zinc-based chemicals, including zinc dust, account for ca. 7 % of the worldwide zinc consumption. Zinc oxide is quantitatively by far the most important zinc-based chemical product, followed by zinc dust, zinc sulphate, and zinc chloride in order of importance and quantity. All other zinc compounds are of minor importance.

Fig. 5.2 Zinc consumption in 2000: first-use and end-use.

Tab. 5.1 Properties, first- and end-use of zinc, data provided by IZA<sup>6</sup>.

| Property                                                                            | First-Use                                                                                   | End-Use                                                                                  |

### 5.3 Cadmium

In recent years, the consumption pattern of cadmium in its various applications has shifted away from the market areas of pigments, stabilisers and coatings to rapidly growing applications in Ni-Cd batteries<sup>7</sup>.

Fig. 5.3 Uses of Cadmium in different applications (reference year 2003<sup>7</sup>)

<sup>6</sup> [http://www.iza.com/zwo\\_org/](http://www.iza.com/zwo_org/), access date 01.03.03

<sup>7</sup> <http://www.cadmium.org>, accessed in April 2007

Description of the different uses of Cadmium <sup>7</sup>:

**Nickel-Cadmium Batteries.** Cadmium hydroxide is utilised as one of the two principal electrode materials in Ni-Cd batteries which have extensive applications in the railroad and aircraft industry for starting and emergency power and in consumer applications such as cordless power tools, cellular telephones, camcorders, portable computers, portable household appliances and toys.

**Cadmium Pigments.** Cadmium sulphide and cadmium sulposelenide are utilised as bright yellow to deep red pigments in plastics, ceramics, glasses, enamels and artists colours. They are used in applications where high temperature or high pressure processing is required.

**Cadmium Stabilisers.** Cadmium-bearing stabilisers retard the degradation processes in polyvinylchloride (PVC) which occur upon exposure to heat and ultraviolet light. These stabilisers contain organic cadmium salts, usually carboxylates such as cadmium laurate or cadmium stearate, which are incorporated into PVC before processing.

**Cadmium Coatings.** Cadmium coatings are utilised on steel, aluminium, and certain other non-ferrous metal fasteners and moving parts to provide the best available combination of corrosion resistance, particularly in salt and alkali media, and lubricity or low coefficient of friction. They are also employed in many electrical or electronic applications where a combination of corrosion resistance and low electrical resistivity are required. In addition, cadmium coatings exhibit excellent plating characteristics on a wide variety of substrates, have good galvanic comparability with aluminium, and are readily solderable.

**Alloys and Minor Uses.** Cadmium alloys include (a) electrical conductivity alloys, (b) heat conductivity alloys, and (c) electrical contact alloys. Other minor uses of cadmium include cadmium telluride and cadmium sulphide in solar cells, and other semiconducting cadmium compounds in a variety of electronic applications.

## 5.4 Indium

Today virtually all of the LCD produced use ITO as conducting layer. ITO is the transparent conductor of choice in terms of high transmissivity of visible light with low electric resistivity compared to other transparent conductors, such as tin oxide (SnO<sub>2</sub>) and zinc oxide (ZnO) (Granqvist & Hultaker, 2002). The sputtering of the substrate is done by the display manufacturers. Due to the very large cost of building TFT factories, the number of major panel vendors is small. Several of the best known are Sharp Corporation, Samsung Electronics, LG.Philips LCD and AU Optronics. As of April 2006, the three biggest manufacturers are LG.Philips and Samsung with 22% of the market, followed by AU Optronics with a 19% share (Wikipedia Contributors, 2006).

Jansseune (2003) estimates that in 2002 45% of the indium supplied went as ITO into coating, whereas 2004 an estimated 72% of the indium was used for ITO coatings (Jorgenson & George, 2004). End 2006 Hewett (2006) estimated the share of ITO in the total indium supply to 80%. In 2004 perhaps 65 %of the indium used in coating goes into display devices, and the remainder, into transparent heat reflection. ITO coatings also are used in architectural glass and solar panel applications (high infrared reflectance), cathode-ray tubes (CRTs), low-pressure sodium lamps, and windshield glass. (Jorgenson & George, 2004).

In 2005 the USGS estimates that 70% of the Indium was used in coatings, electrical components and semiconductors, 12%; solders and alloys, 12%; and research and other, 6% (USGS, 2006a).

**Fig. 5.4** In 2002, the semiconductor industry accounted for 15% of indium consumption, equivalent to around 50,000 kg. Credit: USGS (Jansseune, 2003).

**Fig. 5.5** In 2004 already almost 80% of the indium went into ITO coatings (Teckcominco, 2005).

In 2004 Teckcominco (2005) estimated about 640 tonnes of indium in the end-use, of which ITO coatings amounted to 79% (Fig. 5.5).

### Coatings

Indium's largest use is for coatings. Metallic indium ingots are processed into an oxide and then mixed with tin-oxide to form indium-tin-oxide (ITO). This material is used to produce sputtering targets. These targets are placed in a vacuum and the ITO is "sputtered" onto glass for use in display devices such as laptop computer screens, LCD watches, appliance display panels and portable phones.

ITO is also used in traditional applications such as low-pressure sodium lamps, architectural glass and oven doors (heat reflector applications).

New applications for indium coatings include high definition televisions and thin screen computer monitors (Teckcominco, 2006).

Application of ITO coatings is a wasteful process and only around 20-30% of the material actually ends up on the substrate (Jansseune, 2005). The rest is recycled as prompt scrap.

### Alloys

Indium has a relatively low melting point at 157°C. This enables it to be utilized in alloy production such as AgInSbTe sputtering target manufacturing for the electronics industry (Teckcominco, 2006).

### **Electronics & Semiconductors**

Indium is used as a doping agent for germanium (Ge) and gallium arsenide (GaAs) semiconductors.

The largest use for high purity indium is for the production of indium phosphide (InP) for use in the semiconductor industry. InP is also used in photonic applications, such as lasers, photo detectors, optical modulators and amplifiers, and in electronic applications, such as, HEMT's (high electron mobility transistors), HBT's (heterojunction bipolar transistors), and FET's (field effect transistors), millimeter wave and microwave circuits, and high-speed digital integrated circuits. (Teckcominco, 2006)

## 6 System Characterisation

This chapter describes the mining of sulphidic zinc-lead deposits and the related extraction of lead and zinc but also minor metal values (metals contained in the ore, whose extraction is profitable) such as silver, cadmium and indium for which these deposits represent an important source for worldwide primary production (Silver: 20%, Cadmium: 80%, Indium: ~100%). Therefore, the inventory modelling involves a series of multi-output processes in which all burdens are attributed by economic allocation procedures based on Guinée et al. (2004) and Althaus & Classen (2005) using the average prices from 2004 through 2006 reported by the U.S. Geological Survey (see Tab. 3.1):

- 6.1. The module “mining, zinc-lead-deposit” delivers the flows
  - “lead, concentrate, at beneficiation” (containing silver) and
  - “zinc, concentrate, at beneficiation” (containing cadmium and indium)
- 6.2. The module “smelting, primary lead production” processes the concentrate to the flows
  - “lead, primary, at plant” and
  - “parkes process crust, from desilverising of lead” as an intermediate step for the silver chain
- 6.3. “lead, secondary, at plant”
- 6.4. “lead, at regional storage” (a blend of primary and secondary lead)
- 6.5. The module “smelting, primary zinc production” processes the concentrate to the flows
  - “zinc, primary, at regional storage” (primary production)
  - “cadmium sludge, from zinc electrolysis, at plant” as raw material for cadmium production, and
  - “leaching residues, indium rich, from zinc circuit, at smelter” as raw material for indium production.
- 6.6. “cadmium, primary, at plant”
- 6.7. “indium, at regional storage”

A graphic representation is shown in Fig. 6.1, the boxes with rounded corners represent reference flows from multi-output processes, bold lines denote datasets to be used by the LCA practitioner.

Fig. 6.1 Graphic representation of the modules and flows resulting from the mining of zinc-lead deposits.

Tab. 6.1 Meta information for the mining of zinc and lead bearing ore.

| General Comment to reference function | The module describes the global production mix for jointly produced zinc- and lead-concentrates from sulphidic deposits. The multi output-process "exploitation, zinc-lead-deposit" delivers the co-products "lead, concentrate, at beneficiation" and "zinc, concentrate, at beneficiation". It is designed for the use of the concentrates as raw material for the ultimate production of lead and zinc. |

| Geography text                        | This module represents a global production mix. Some agents used like lime or sodium cyanide originate from data sets valid for Switzerland or Europe. Processes like blasting and transport originate from data sets valid for Switzerland or Europe.                                                                                                                                                     |
| Technology text                       | This module is approximated with values from nickel-mining. Mining is assumed to be underground, followed by froth beneficiation. Overburden and tailings are disposed inside the mining panels. For electricity mix a mix of 25% coal and 75% gas fired plants was chosen.                                                                                                                                |
| Representativeness [%]                |                                                                                                                                                                                                                                                                                                                                                                                                            |

| General Comment to reference function | The module describes the primary production of lead in Europe. The multi-output-process "Smelter, primary lead production" delivers the co-products "Lead, primary, at plant" and "Parkes process crust, from desilverising of lead".. The flow "Lead, ..." is part of the respective European supply mix. The by-product "Parkes process crust, ..." receives part of the burden and enters the silver production chain. | The module describes the production of secondary lead in Europe. The feed of secondary material consists of scrap lead acid (PbA) batteries from automobiles. The data refers to one big operation in Europe that operates with representative technology. | This dataset describes the supply mix of lead used in Europe. It is modelled with a blend of 25% primary and 75% secondary production, complemented with the transport service required to transport the material to the regional storage. In the global average the secondary production amounts only 65%. |
| Start Date                            | 2000                                                                                                                                                                                                                                                                                                                                                                                                                      | 2000                                                                                                                                                                                                                                                       | 2000                                                                                                                                                                                                                                                                                                        |

| Included Processes                    | The module includes the production of high grade (SHG) primary zinc by pyro- and hydrometallurgical processes, the disposal of the slag and the treatment of the waste water. No secondary production - which amounts to 30% in Europe - is considered.                                                                                                                                                                                                                                                                       |

| General Comment to reference function | The module describes the primary production of zinc in Europe. The multi-output-process "smelting, primary zinc production" delivers the three co-products "zinc, primary, at regional storage", "cadmium sludge, from zinc electrolysis, at plant" and "leaching residues, indium rich, from zinc circuit, at smelter". The flow "zinc, ..." represents the European supply mix of primary zinc. The by-products "leaching residues, ..." and "zinc, ..." receive part of the burden and enter the primary production chain. |
| CAS Number                            |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |

| General Comment to reference function | The module describes the primary production of cadmium metal (99.9%) on a global average. No secondary sources from post consumer scrap are considered. Only the most important source, the cadmium sludges from hydrometallurgical zinc operations, is reflected with the dataset. For the use in applications where cadmium is a major constituent – e.g. in NiCd battery systems – the dataset should be complemented with additional specific emission factors and the secondary production process.. |

| Included Processes                    | The module includes the production of indium from zinc extraction operations. Infrastructure and transports to Europe are considered. Most process specific emissions are missing.                                                                                                                                                                                                                                                                                                                                                              |

| General Comment to reference function | The module describes the primary production of indium metal (99.999%, 5N) on a European average. No secondary sources from post consumer scrap are considered. Only the most important source of indium raw material, the hydrometallurgical zinc operations, is reflected with the dataset. This dataset is based on the respective flow from multi-output module "smelting, primary zinc production". This dataset is not to be used when indium is a substantial part of the system modelled, viz. for comparisons of special solder pastes. |

| Geography text                        | This module represents the production of primary indium for the consumption in Europe. The inventory however is compiled with global average data, e.g. for zinc-production.                                                                                                                                                                                                                                                                                                                                                                    |
| Technology text                       | Indium containing residues from hydrometallurgical zinc operations are leached. Subsequent solvent extraction and precipitation of sponge indium. Indium cathodes are cast and electrorefined, followed by vacuum refining to obtain 5N quality. Solvent-extraction and electrowinning has been extrapolated from copper refining.                                                                                                                                                                                                              |
| Representativeness [%]                |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |

## 6.1 Mining of zinc-lead-deposits

About 70 % of zinc and the same amount of lead is won from a sulphidic ore, where the elements occur jointly. They are also jointly extracted.

### 6.1.1 Production process and infrastructure

Zinc-lead ores are assumed to be mined mostly underground. The ore is transferred to the beneficiation. Widening of the tunnels is mainly done by blasting. The overburden – material, which does not contain metal-bearing ore – is partly deposited off-site and partly refilled into the tunnels.

After mining, the ore is firstly ground. In a next step it goes through gravity concentration to separate the metallic particles from the metal bearing minerals. After this first concentration step, flotation is carried out to remove the gangue from the sulphidic minerals. For neutralisation lime is added. In the flotation several organic chemicals are used as collector, frother, activator, depressor and flocculant. Sometimes cyanide is used as depressant. Tailings are usually transferred to tailing heaps or ponds. Concentrates are produced containing around 50% zinc and 50% lead.

### 6.1.2 Waste

The overburden is disposed of close to the mine. Tailings are deposited as piles and in ponds. In both the overburden and the tailings acid rock drainage occurs over a long period of time. These effects are handled in the part IX (Non Ferrous Metal Winning – Auxiliary Processes, chapter Disposal of Tailings and Overburden) of this report.

### 6.1.3 Emission

The major emissions are mineral born pollutants in effluents and dust. The prevalently underground mining operations generate roughly 80 % of the dust emissions from surface operations, since the major dust sources do not take place underground. Rain percolates through the overburden and generates metal leachates to groundwater.

Ore handling and processing produce large amounts of dust, containing PM<sub>10</sub> and several metals from the ore itself. Flotation produces effluents containing several organic agents<sup>8</sup> used. Some of these chemicals evaporate and account for VOC emissions to air. In particular, xanthates decompose hydrolytically to release carbon disulphide. Tailings effluent contains additional sulphuric acid from acid rock drainage.

### 6.1.4 Mining, zinc-lead deposits in ecoinvent

Since the extraction of zinc and lead is very similar to the extraction of other sulphidic deposits like nickel and copper bearing ores, and no information on the specific mining processes for zinc-lead deposits is available, the data for the exploitation of nickel provided in Hilbrans & Hinrichs (1999) was used. Mass flows were adjusted to values specific to zinc-lead extraction, according to information given in Ayres et al. (2002).

---

<sup>8</sup> Floating agents consist of collectors (xanthate or aerofloat) and frothing reagent (eg. Methyl Isobutyl Carbinol). Xanthates are a broad class of organic salts formed by treatment of an alcohol with carbon disulfide in the presence of an alkali, potassium ethyl xanthate (KC<sub>3</sub>H<sub>5</sub>S<sub>2</sub>O, CAS No: 140-89-6). Aerofloat is a salt of carbonyldithiophosphoric acids. A widely used frothing reagent is e.g. methyl isobutyl carbinol, CAS: 108-11-2, syn. Methyl Amyl Alcohol.

The module describes the global production mix for jointly produced zinc- and lead-concentrates from sulphidic deposits. The multioutput-process “exploitation, zinc-lead-deposit” delivers the co-products “lead, concentrate, at beneficiation” and “zinc, concentrate, at beneficiation”. It is designed for the use of the concentrates as raw material for the production of lead and zinc. The layout of the modules with general flow information, remarks, sources, values and uncertainty information is shown in Fig. 6.3 and Fig. 6.4. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one kg of added zinc- and lead-concentrates. The meta-information for this dataset is compiled in Tab. 6.1

Fig. 6.2 gives an overview of the general assumptions made in the mass flows of this module. It is assumed, that two virtually distinctive concentrate products are produced. This of course is not true in real production, but it is a formal necessity for the further use in ecoinvent in the modules for zinc and lead production.

The range of concentrate composition described varies considerably. Depending on the processing technology, a high degree (60-75% of a single metal, lead or zinc) concentrate may be required. Most smelters accept lower grade concentrates that range 50-60% Pb (e.g. Trail, Mt. Isa). In this study a content of 55% Pb in the concentrate is chosen. The range of zinc content reported in zinc concentrates is much narrower than for lead. A compilation of concentrates of 80 mines in (Rodier, 1990) showed a range between 45 and 60% Zn, with a mean value of 53%. Reuter (2005) states an average zinc concentrate to have 50% Zn and uses 54% in his calculations.

In order to comply with the global production figures the assumption is made that not all of the minor metals cadmium and indium are not entirely recovered. Only a share of the extracted volume is worked for these metals, the other operations discard these metal values with the gangue. This is represented by the percentages in white colour in the input arrow in Fig. 6.2.

**Fig. 6.2** Basic assumptions for the mining process of zinc- and lead ore from sulphidic deposits. Values relate to the production of the sum of 1 tonne metals contained in the concentrate, they are mainly taken from Ayres et al. (2002) and IPPC (2001).

### Infrastructure and land use

The infrastructure used for ore exploitation is inventoried within this module, whereas the infrastructure like buildings and land-use for the operation is inventoried in another appropriate module, comprising both mining and beneficiation facilities. The mobile equipment used for exploitation like drilling machines, scoop trams and underground trucks is inventoried through their diesel consumption. The module used for this purpose “diesel, burned in building machine” includes the infrastructure of the machines. Additionally, 2000 m conveyor belts are assumed with a capacity of 2000 t/h which yields  $2 \cdot 10^{-5}$  m conveyor belt required per tonne mined raw ore.

Since mining is underground and no heap leaching is done, no land use for exploitation is assumed.

**Tab. 6.6** Infrastructure in underground mining, assumptions used. A lifetime of ten years and 5000 working hours yearly are estimated.

| action    | machine        | throughput lifetime | unit       | Infrastructure    |
|-----------|----------------|---------------------|------------|-------------------|
|           |                | Mass (t)            | Length (m) | m/t ore mined     |
| Transport | Conveyor belts | 100'000'000         | 2000       | $2 \cdot 10^{-5}$ |

## Mining

In the considered processes the ore is mined underground. The overburden is disposed in piles near the mine, for which the standard module for disposal of sulphidic overburden has been chosen, which includes the land use and land transformation by the disposal. Overburden refilled into the mine is assumed to be burden free. The degree of the refilling is documented for extraction of nickel-ores in Hilbrans & Hinrichs (1999). This source is also used for water use and effluent volume from mining. The use of freshwater was inventoried as river water, whereas the pit water was assumed to be groundwater, which has to be pumped out. The composition of a generic effluent from mines was taken from IPPC (2002), its values are shown in Tab. 6.8. No waste-water treatment is considered. No information on the energy production in mining is available. In many cases the electricity used in the often remote mining operations is made on site by gas or coal fired power plants. In this study a split of 75% gas fired and 25% coal fired plants was assumed based on own estimations. Specific values and corresponding inventory flows are shown in Tab. 6.7. Cement, explosives and sand are assumed to be transported by lorry over 100 km.

For refilling the pit, apart from overburden additional stowing material – mostly sand – and cement are used.

## Beneficiation

Once the ore is mined, it is ground and conditioned for subsequent concentration. Considerable amounts of lime and flotation agents are added. The separated gangue is disposed in tailings ponds, the concentrated ore is fed to the metallurgy, which is assumed to be on-site.

The infrastructure of beneficiation is included in mining infrastructure. Dust emissions comprise additionally the dust emissions due to mining activities. Like in the mining step, a share of 60% hydroelectricity was chosen according to Hilbrans & Hinrichs (1999).

**Lime:** Lime input is documented in Hilbrans & Hinrichs (1999) for the beneficiation of lead-/zinc-sulphide, the input of 554 g / t ore is taken from the specific input in nickel beneficiation.

**Reagents:** No information on the nature and mass of the floating agents used is available. For copper mining a range of 25 – 300 g collector and 25 – 250 g frothing reagent per ton sulphidic ore is recommended (Krauss et al., 1999). This is confirmed by the values in Tab. 6.9. Collector and frother are balanced in ecoinvent as unspecified organic chemical. According to NPI (2001) xanthates hydrolytically decompose to 0.53 mg carbon disulphide per mg xanthate. With 189 mg xanthates from Tab. 6.9 this is about 100 mg carbon disulphide per t mined ore. This again is modelled as unspecific organic chemical.

Activator and Depressants – excluding sodium cyanate – are modelled as unspecific inorganic chemicals. Their emission to water is covered by reported emissions from mining sites shown in Tab. 6.8.

For pH adjustment and leaching, sulphuric acid is considered with 3.74 kg / t ore mined (Tab. 6.10). As sulphuric acid is a by-product from the metallurgy, its production is regarded in ecoinvent as burden free. Other acids are neglected.

Since composition and environmental fate of activator, depressant and sulphuric acid are uncertain, reported data for total effluents shown in Tab. 6.8 are taken.

Sodium cyanide is widely used for extracting gold and other metals such as silver, copper and zinc. It is used as leachate and as depressant for certain sulphidic minerals. A cyanide recovery of 80 – 90% is reported due to abatement and recovery in the Golden Cross mine in New Zealand (Anonymous, 1998). Here a value of 80% is chosen for cyanide-abatement technology. With a reported use of 35 g NaCN per tonne ore mined (Tab. 6.9) this means a direct emission of 3.75 g CN<sup>-</sup> per tonne ore mined. An overview of the reagents accounted for is presented in Tab. 6.9.

**Effluents:** Additional to direct emissions due to the use of chemicals, emissions to water are chosen according to Tab. 6.8. These values are from base metal sites, thus only an approximation for the real effluent concentrations in the zinc / lead extraction. It is assumed here that the effluents also include acid rock drainage (ARD). ARD after mine closure is modelled in the module “disposal, sulphidic tailings, off-site”.

**Dust:** The dust emissions are approximated in both amount and particle distribution approximated with specific values from copper mining from the CEPMEIP-Database<sup>9</sup>. According to IAEA<sup>10</sup> the dust composition is approximated with concentrations of the zinc-lead-ore (Tab. 6.11). The dust emissions are summed up in Tab. 6.11. In ecoinvent, for particulates three different classes are used, whose total corresponds to the total dust emission.

**Tab. 6.7** specific input and effluent values used and their corresponding value per t concentrate established in this inventory. The specific values are approximated by values from sulphidic nickel deposits (Hilbrans & Hinrichs, 1999).

**Tab. 6.10 Emissions and input due to chemical use in beneficiation in g per tonne treated ore. The values are the ones chosen in this study. For further details read in text and Tab. 6.9.**

| Reagent              | Type of burden     | Unit | Chosen value |
|----------------------|--------------------|------|--------------|
| Collector            | input technosphere | g/t  | 189          |
| Carbon disulfide     | air emission       | g/t  | 100          |
| Frother              | input technosphere | g/t  | 37           |
| Lime                 | input technosphere | g/t  | 554          |
| Carbon dioxide       | air emission       | g/t  | 244          |
| Activator/Depressant | input technosphere | g/t  | 828          |
| Sulphuric acid       | input technosphere | g/t  | 3739         |
| Sodium Cyanide       | input technosphere | g/t  | 35.2         |
| Cyanide              | water emission     | g/t  | 3.75         |

**Tab. 6.11 Emissions to air resulting from mining activities per tonne mined ore. Approximated values derived from reported emission factors from copper extraction and a single ore composition. Values for total dust emission and, partition of fractions of particulate matter are taken from the CEMIP-database, the dust composition correspond to a specific nickel sulphide with values taken from the IAEA-database (see text).**

| Emission to air | Unit      | Emission / t ore |
|-----------------|-----------|------------------|
| Cadmium         | g / t ore | 0.102            |
| Lead            | g / t ore | 5.1              |
| Zinc            | g / t ore | 9.2              |
| Sulphur         | g / t ore | 10.2             |
| PM<2.5          | g / t ore | 5.0              |
| PM2.5-10        | g / t ore | 45               |
| PM>10           | g / t ore | 52               |
| total dust      | g / t ore | 101.72           |

## Allocation

According to the allocation principle pursued throughout the inventory modelling in this report, an economic allocation for the joint by-products lead and zinc concentrate is envisioned. Since beside the main constituents lead and zinc, also silver, cadmium and indium are present in the products, also these values have to be considered. Cadmium is considered contaminant and therefore does not affect the allocation procedure, since it does not receive a value within the zinc production. The cadmium containing wastes become valuable only after refining.

**Tab. 6.12 Overview over the relevant parameters to determine the allocation split: composition of the by-products and value of the metals contained.**

|                       | <b>Zinc concentrate</b> | <b>Lead Concentrate</b> | <b>Value in \$ / kg</b> |
|-----------------------|-------------------------|-------------------------|-------------------------|
| feed in kg            | 0.699                   | 0.301                   |                         |
| Pb in kg              | -                       | 0.166                   | 1.26                    |
| Zn in kg              | 0.370                   | -                       | 3.09                    |
| Ag in kg              | -                       | 3.29E-04                | 360                     |
| Cd in kg              | 0.0023                  | -                       | contaminant             |
| In in kg              | 6.03E-05                | -                       | 855                     |
| Value contained in \$ | 1.19                    | 0.33                    |                         |
| Allocation by value   | 79%                     | 21%                     |                         |
| Allocation by mass    | 70%                     | 30%                     |                         |

### 6.1.5 Data quality

Data uncertainty is derived using the pedigree matrix as described in Frischknecht et al. (2004). The inventory is fully based on values from nickel-mining reported in Hilbrans & Hinrichs (1999), which may eventually bias the assertions. For specific conclusions further investigation especially on the effluents composition and tailings emissions has to be done. The uncertainty of emissions that are adopted from nickel mining is arbitrarily reflected by a geometric standard deviation of 10. The choice of electricity mix bases on assumptions that have to be improved with further investigations.

## 6. System Characterisation

## 6.2 Primary Lead Production Process and Infrastructure

There are two basic pyrometallurgical processes available for the production of lead from lead or mixed lead-zinc-sulphide concentrates: sinter oxidation / blast furnace reduction route or Direct Smelting Reduction Processes.

### 6.2.1 Production process and infrastructure

Both processes may also be used for concentrates mixed with secondary raw materials. Both processes are followed by a refining step to produce the final product with the required purity (Sutherland et al., 1997; IPPC, 2001).

The sinter oxidation / blast furnace reduction involves two steps:

- 1) a sintering oxidative roast to remove sulphur with production of PbO; and,
- 2) blast furnace reduction of the sinter product.

The objective of sintering lead concentrates is to remove as much sulphur as possible from the galena and the accompanying iron, zinc, and copper sulphides, while producing lump agglomerate with appropriate properties for subsequent reduction in the blast furnace (a type of a shaft furnace).

As raw material feed, lead concentrates are blended with recycled sinter fines, secondary material and other process materials and pelletised in rotating drums. Pellets are fed onto sinter machine and ignited. The burning pellets are conveyed over a series of wind-boxes through which air is blown. Sulphur is oxidised to sulphur dioxide and the reaction generates enough heat to fuse and agglomerate the pellets.

Sinter is charged to the blast furnace with metallurgical coke. Air and/or oxygen enriched air is injected and reacts with the coke to produce carbon monoxide. This generates sufficient heat to melt the charge. The gangue content of the furnace charge combines with the added fluxes or reagents to form a slag.

For smelting bulk lead-zinc-concentrates and secondary material, frequently the Imperial Smelting Furnace is used. Here, hot sinter and pre-heated coke as well as hot briquettes are charged. Hot air is injected. The reduction of the metal oxides not only produces lead and slag but also zinc, which is volatile at the furnace operating temperature and passes out of the ISF with the furnace off-gases. The gases also contain some cadmium and lead. The furnace gases pass through a splash condenser in which a shower of molten lead quenches them and the metals are absorbed into the liquid lead, the zinc is refined by distillation.

The Direct Smelting Reduction Process does not carry out the sintering stage separately. Lead sulphide concentrates and secondary materials are charged directly to a furnace and are then melted and oxidised. Sulphur dioxide is formed and is collected, cleaned and converted to sulphuric acid. Carbon (coke or gas) and fluxing agents are added to the molten charge and lead oxide is reduced to lead, a slag is formed. Some zinc and cadmium are “fumed” off in the furnace, their oxides are captured in the abatement plant and recovered.

Several processes are used for direct smelting of lead concentrates and some secondary material to produce crude lead and slag. Both smelting processes are used: the ISA Smelt/Ausmelt furnaces (sometimes in combination with blast furnaces), Kaldo (TBRC) and QSL integrated processes are used in EU and Worldwide. The Kivcet integrated process is also used and is a flash smelting process. The ISA Smelt/Ausmelt furnaces and the QSL take moist, pelletised feed and the Kaldo and Kivcet use dried feed.

**Refining:** Lead bullion may contain varying amounts of copper, silver, bismuth, antimony, arsenic and tin. Lead recovered from secondary sources may contain similar impurities, but generally antimony and calcium dominate.

There are two methods of refining crude lead: electrolytic refining and pyrometallurgical refining. Electrolytic refining uses anodes of de-copperised lead bullion and starter cathodes of pure lead. This is a high-cost process and is used infrequently. A pyrometallurgical refinery consists of a series of kettles, which are indirectly heated by oil or gas. Over a series of separation processes impurities and metal values are separated from the lead bouillon.

### 6.2.2 Waste

The production of metals is related to the generation of several by-products, residues and wastes, which are also listed in the European Waste Catalogue (Council Decision 94/3/EEC). The ISF or direct smelting furnaces also are significant sources of solid slag. This slag has been subjected to high temperatures and generally contains low levels of leachable metals, consequently it may be used in construction. Solid residues also arise as the result of the treatment of liquid effluents. The main waste stream is gypsum waste ( $\text{CaSO}_4$ ) and metal hydroxides that are produced at the wastewater neutralisation plant. These wastes are considered to be a cross-media effect of these treatment techniques but many are recycled to pyrometallurgical process to recover the metals. Dust or sludge from the treatment of gases are used as raw materials for the production of other metals such as Ge, Ga, In and As, etc or can be returned to the smelter or into the leach circuit for the recovery of lead and zinc. Hg/Se residues arise at the pre-treatment of mercury or selenium streams from the gas cleaning stage. This solid waste stream amounts to approximately 40 - 120 t/y in a typical plant. Hg and Se can be recovered from these residues depending on the market for these metals.

### 6.2.3 Emission

The main emissions to air from zinc and lead production are sulphur dioxide, other sulphur compounds and acid mists; nitrogen oxides and other nitrogen compounds, metals and their compounds; dust; VOC and dioxins. Other pollutants are considered to be of negligible importance for the industry, partly because they are not present in the production process and partly because they are immediately neutralised (e.g. chlorine) or occur in very low concentrations. Emissions are to a large extent bound to dust (except cadmium, arsenic and mercury that can be present in the vapour phase).

Metals and their compounds and materials in suspension are the main pollutants emitted to water. The metals concerned are Zn, Cd, Pb, Hg, Se, Cu, Ni, As, Co and Cr. Other significant substances are fluorides, chlorides and sulphates. Wastewater from the gas cleaning of the smelter and fluid-bed roasting stages are the most important sources.

### 6.2.4 Smelting, primary lead production in ecoinvent

No contiguous study on the lead production is yet available, therefore this module is based partly on values reported in Ayres et al. (2002), IPPC (2001), Xiao et al. (2003), and EEA (1999a).

The module describes the primary production of lead in Europe. The multi-output-process "smelting, primary lead production" delivers the co-products "lead, primary, at plant" and "parkes process crust, from desilverising of lead". The flow "lead, ..." is part of the respective European supply mix. The by-product "parkes process crust, ..." receives part of the burden and enters the silver production chain.

The modules including general flow information, remarks, sources, values, and uncertainty information are shown in Fig. 6.5 (inputs) and Fig. 6.6 (outputs). The following sections describe calculations, sources and assumptions chosen in this study. The meta-information for this dataset is compiled in Tab. 6.2.

The smelting process is modelled as a combination of the two predominant processes

- Sinter oxidation / blast furnace reduction (44% of world production, Tab. 6.13), and the newer

- Direct smelting process (QSL, Kivcet, etc., 56% of world production, Tab. 6.14)

The inputted raw materials and the emission factors are combined according to the production share in order to for the inventory in ecoinvent (Fig. 6.5 and Fig. 6.6). No quantitative compilation of electricity production is available, therefore the UCTE production mix was chosen as approximation (year 2000: nuclear 15%; hydro 4%; fossil 81%<sup>11</sup>).

The two predominant processes differ also in emission factors per tonne lead produced. Where the older sinter oxidation / blast furnace processes exhibit limited abatement possibilities, higher emissions occur from these (Tab. 6.15). The more recent direct smelting processes in contrast have improved emission control (Tab. 6.16). The combination of the two process technologies combined according to their production shares gives the emission factors used in this inventory (Tab. 6.17). Some of the emissions generally reported in literature and stated in the previous section – Ge, Ga, In, Se, acid mists, VOC (air); fluorides, chlorides and sulphates (water) – are not covered by this inventory because no emission factors could be found. The dioxin emissions are approximated with the reported emission factor of 50 µg-TEQ / t secondary zinc production in EC (2002).

**Tab. 6.13 Lead production: Sinter oxidation / blast furnace reduction. Input / output and energy demand reported from various sources. ISF = Imperial smelting furnace. 44 % of the lead production, emission factors in this table are combined with 56 % direct smelting in Tab. 6.14**

| COD               | g / t | 583                |

### 6.2.5 By-products and allocation

Argentiferous lead and lead-zinc ores, which often occur in association, are distributed widely. In almost all silver-producing countries, they constitute an important fraction of the silver produced by mining and account for ca. 50 % of world silver production (Renner et al., 2002).

Mine production remains by far the largest contribution to silver supply, normally accounting for around two-thirds of the total. Beside mine production, post consumer scrap, disinvestment, government sales and producer hedging are sources for supply. Old scrap normally makes up a little over a fifth of the supply (Klapwijk et al., 2006).

The ratio between the world supply of silver and the world mine production of lead amounted in the last twenty years between four to six kilograms silver per tonne lead mined (s. Tab. 3.1). This leads to the assumption that in a world average per tonne lead mined 2.3 kg silver is jointly extracted and refined.

By the so-called Parkes process a silver containing crust arises where silver is accumulated and subsequently refined further (Renner et al., 2002). A metallurgical process Ag yield of 97.4% is assumed (Reuter, 2005). For more details on the process, see the respective chapter on Silver in this report.

However, the allocation of the subprocesses lead- and silver production is not evident to solve, since only the final commodity prices are known but no in-firm prices for the crust and for the raw lead bullion, on which the allocation would rely. Also the share of the products in total costs – gross sales method as proposed in Guinée et al. (2004) and Guinée et al. (2001) – is not easy to estimate. The by-product allocation problem – the joint production of silver and lead – is tackled here by a subdivision of the sub-processes (according to Ekvall & Finnveden, 2001). The silver production from the parkes process crust is treated in a distinct inventory. Hence the burdens have to be allocated between the lead and the silver containing crust.

As starting point for an estimation it is assumed that the profit margin for the production of silver corresponds to the company's performance. Taking an arbitrary performance value of 10% - which reflects the general profit expectations of major enterprises – the value of the crust corresponds consequently to 10% of the proceeds from the silver sales. Therefore 10 % of the silver price is taken to estimate the value of the silver containing Parkes process crust.

The composition and the corresponding values contained in the by-products result in a split of 4% to the silver and 96% to the lead (Tab. 6.20).

However, the resources (elementary flows) have to be allocated by mass to the respective by-products, in order to keep up with the resource balance in the final commodity. Since the concentrate required by this multi-output-process is allocated also by revenue, the therein contained resources are not correctly attributed and have to be corrected with a corrective exchange flow (Tab. 6.21).

**Tab. 6.20 By-products of primary lead production: Composition, flows and value to derive the revenue-based allocation factors (Values are the year averages from 2004 through 2006, reported by the U.S. Geological Survey)**

## 6.2.6 Data quality

Data uncertainty is derived using the Pedigree matrix as described in Frischknecht et al. (2004). Some of the emissions that are described in the literature as typical for lead, could not be covered in this inventory due to missing emission factors, namely Ge, Ga In and Se into air and , Zn, Se, Cu, Ni, Co and Cr to water. Also salts – fluorides, chlorides and sulphates – are not included due to missing data. Further investigations on these issues have been done to improve the quality of this dataset. However, for the purpose of a background database the quality is sufficient. The choice of electricity mix bases on assumptions that have to be improved with further investigations.

Fig. 6.6 Flows for "Smelting, primary lead production " (outputs) and its representation in the ecoinvent database

## 6.3 Secondary Lead Production process and infrastructure

Secondary lead originates to a predominant share from spent lead acid (PbA) batteries. Gabby (2004) estimates 92% for this source in the U.S. in 2004. Lead acid batteries' recycling is very similar to the primary lead production process. The main differences are in material preparation before reduction, which affects plant size, since there is no need for sintering (Espinosa et al., 2004).

The processing of this sort of scrap can be done by different technologies. The classical way makes use of short or long rotary furnace (Various Authors, 1996). More recently the convergence of primary and secondary producer has led to hybrid systems that process simultaneously both lead ore and metallic post consumer scrap lead. One example is the QSL process at the Bleihütte Binsfelderhammer in Stolberg, Germany (Berzelius, 1993).

### 6.3.1 Lead, secondary, at plant in ecoinvent

This dataset describes the recovery of secondary lead from spent lead acid batteries as done at Campine, Belgium (Campine NV, 2006). The company uses a shaft furnace with post combustion (Quirijnen, 1999). The compilation of the unit process LCI as applied in ecoinvent is displayed in Tab. 6.22. The meta-information is reported in Tab. 6.2, at the beginning of this chapter.

Typically this technology produces 5000 t / a sulphuric acid (15% concentration), 25'000 t lead bullion (98% Pb), 1200 t / a slags (1% Pb) and 3000 t / a raw lead matte (10% Pb) to be shipped to primary smelters. Overall Pb yield is typically 98.8% at the plant level and 99.8% after reworking the matte (Quirijnen, 1999).

The operation treats junk batteries and plates but also lead cable sheathing, drosses and sludges, leaded glass and balancing weights. From this feed it manufactures mainly antimonial lead up to 10% Sb, calcium-aluminium lead alloys with or without tin and soft lead with low and high copper content. All these products are the result of a refining and alloying step to meet the compliance with the designations desired. For the purpose of this LCI-module all these alloys are subsumed under the reference flow "lead, secondary, at plant". The company deliveries amounted in 2004 and 2005 around 40'000 t lead per year, which represents ca. 0.8% of the world secondary lead production (estimated 5'000'000 t in 2005 (USGS, 2006b)).

The inventory data for the process has been adopted from the Battery LCA commissioned by the UK Department for Environment Food and Rural Affairs (Defra), prepared by Fisher et al. (2006). It represents data for Campine Ltd from 2004 (Tab. 6.22).

The values for the energy carriers have been converted in effective heat delivered with the respective energy content and energy efficiency as given in ecoinvent Centre (2005) and Frischknecht et al. (2004). The datasets consider the system specific combustion emissions, therefore the originally reported CO<sub>2</sub> emissions – mainly due to the combustion – are omitted for LCI calculation. It is not clear whether the emissions from SO<sub>2</sub> emissions are due to the combustion. Assuming a heavy fuel burner in Jungbluth (2003) with quite high SO<sub>2</sub> emissions (0.005 kg SO<sub>2</sub> per kg CO<sub>2</sub> emitted in off-gas.), only 35 % of the reported SO<sub>2</sub> emissions may be explained. Therefore it is assumed, that the SO<sub>2</sub> emissions originate from a process other than combustion and is counted for as indicated in Fisher et al. (2006).

The infrastructure has been approximated with the generic module for non-ferrous metal operations with 2'650'000 t/a output and 50 a life time. Transportation of the raw material is considered in the dataset "iron scrap, at plant" that is used as approximation for collection and preparation of the battery scrap. The rest of the auxiliary material, energy carrier, as well as the disposal of the slag is assumed to occur by lorry over 100 km distance.

Tab. 6.22 Unit process data for “lead, secondary, at plant” as given in Fisher et al. (2006).

| Flow                              | Quantity  | Unit | Comments / Inventory used                                                   |

### 6.3.2 Data quality

Data uncertainty is derived using the Pedigree matrix as described in Frischknecht et al. (2004). As there is one facility that has to stand for a variety of technologies applied, the reliability and correctness of the data set is limited and may not be applicable to life cycle assessment studies of products where the production of secondary lead becomes important.

## 6. System Characterisation

## 6.4 Lead, at regional storage in ecoinvent

This dataset describes the supply-mix of lead used in Europe. Following the recycled content approach it consists of a blend of the datasets for primary and secondary production, complemented with the transport service required to transport the material to the regional storage. The meta-information is compiled on Tab. 6.2 at the beginning of this chapter.

As indicated in Section 2.2 *Lead as secondary resource* the primary production of lead has seen a decline in recent years due to more stringent regulations in the use of lead. Since no actual (2007) figures are available, the value of 58% secondary lead in 2001 is taken as starting point. CHR Metals assumed in 2001 the decline in global lead mine production with a small increase thereafter and a respectively higher secondary production that satisfies the gap in supply (Roberts, 2003). The mine production data shows such a small decline in 2002 and a slow increase after that year. On the other hand the reported metal production increased faster, indicating that – under the assumption that no considerable stocks are being consumed, viz. steady state situation – also the secondary production has risen moderately. This reasoning leads to an estimated 65% secondary lead in the global supply mix, compared to 70 – 80% as reported for the U.S. in the years from 2003 – 2006 (USGS, 2006b). A value of 75% is adopted for the European dataset (country-code RER).

Average transport distances have been assumed to depict the European situation (Tab. 6.23).

## 6.5 Primary Zinc Production Process

Zinc can be produced from primary raw materials by pyrometallurgical or hydrometallurgical methods (Fig. 6.9). Pyrometallurgical methods are used in other parts of the world but have gradually lost their importance and are not used in EU for simple zinc concentrates. Determining factors for this tendency are the need for an extra distillation stage to obtain high-grade zinc and the relatively low zinc extraction efficiency. The pyrometallurgical Imperial Smelting Furnace process (ISF) is however still of importance in EU because it enables complex lead-zinc concentrates and secondary material to be treated simultaneously, yielding saleable lead and zinc. It can also consume residues from other processes (IPPC, 2001).

Fig. 6.9 General scheme of zinc production (Dove & Boustead, 1998). The pyrometallurgical and hydrometallurgical production processes account for 20% and 80% of the world production, respectively (IPPC, 2001).

### 6.5.1 Production process and infrastructure

The pyrometallurgical route is used for feed of mixed zinc/lead concentrates and secondary material and uses the Imperial Smelting Furnace (ISF), a special form of a blast furnace. The electrothermic furnace is used in other parts of the world. Zinc produced in the Imperial Smelting Furnace may contain varying amounts of cadmium, lead, copper, arsenic, antimony and iron. The process uses a refining stage. Zinc from the ISF is refined by reflux distillation in columns containing a large number of refractory trays (New Jersey Distillation). The lower ends of the columns are heated externally by natural gas. The upper ends are not heated and run cool enough to reflux the higher boiling point metals before vapours pass to a condenser. The New Jersey distillation column is also used for secondary zinc materials. Distillation proceeds in two stages; first the separation of zinc and cadmium from lead and then separation of cadmium from zinc. In the first stage, molten zinc is fed into a column where all the cadmium and a high proportion of the zinc are distilled. The mixture is condensed and fed directly to a second column. This column is operated at a slightly lower temperature to distil mainly cadmium, which is condensed as a zinc-cadmium alloy. The alloy is transferred to a cadmium refinery. The

metal run-off from the bottom of the second column is high-grade zinc (SHG) of 99.995% purity. The run-off metal from the first stage is zinc with lead, tin, arsenic, iron, antimony and copper impurities. This alloy is cooled to separate lead, which is recycled to the ISF splash condenser and an inter-metallic compound of iron, zinc and arsenic, which is recycled to the ISF itself. The zinc is then treated with sodium to remove residual arsenic and antimony as sodium arsenides and antimonides, respectively, which are also recycled to the ISF. The zinc produced in this way is of a lower grade (GOB), but free of cadmium, and is used mainly for galvanising (IPPC, 2001).

**Fig. 6.10** Process scheme, part of the pyrometallurgical process route (rectification). The residues of the first stage distillation are processed to GOB Zinc (lowest quality, “Good Ordinary Brand”), which is used for galvanising, whereas the SHG Zinc (highest quality, “Special High Grade”) is won by a second distillation (IPPC, 2001)

The hydrometallurgical route is used for zinc sulphide, oxide, carbonate or silicate concentrates, making about 80% of the total world output. The majority of the EU production facilities use the hydrometallurgical process, with a total production capacity of 1'665'000 t/a in 1997. Sulphide concentrates are roasted first in fluidised bed roasters to produce zinc oxide and sulphur dioxide. Roasting is an exothermic process and no additional fuel is used to sustain the reaction, the heat generated is recovered. The zinc oxide (calcine) passes from the furnace and is collected and cooled. Roaster gases are treated in hot electric precipitators to remove dust (which is passed to the calcine). Other dust and volatile metals such as Hg and Se are removed in a gas cleaning train that incorporates scrubbing systems and wet EPs. The sulphur dioxide is then converted to sulphuric acid in a conventional recovery system. Leaching of the calcine is carried out in a number of successive stages using a gradually increasing strength of hot sulphuric acid. The initial stages do not dissolve significant amounts of iron but the later ones do. The leaching process is carried out in a variety of reactors using open tanks. Leaching may be stopped after the neutral leach. The leach residue is sent to an ISF and added to the sinter feed. Zinc, lead and silver are recovered as metals, sulphur as H<sub>2</sub>SO<sub>4</sub>. Instead of an ISF, a Waelz Kiln may be used but SO<sub>2</sub> absorption is necessary in such a case. Other metals are also dissolved during the process and are removed after leaching. Iron is the major impurity, which is precipitated in three basic forms; Jarosite, Goethite or Haemetite (IPPC, 2001). Zinc produced hydrometallurgically does not need to be refined (Graf & Schleining, 1997).

### 6.5.2 Waste

The production of metals is related to the generation of several by-products, residues and wastes, which are also listed in the European Waste Catalogue (Council Decision 94/3/EEC). The electrolytic production of zinc is one of the main sources of solid waste in the non-ferrous industry. Relatively

large quantities of iron based solids are generated by the leaching process. Jarosite and goethite are classified as hazardous waste because of the content of leachable elements such as Cd, Pb and As. The leaching and purification processes and electrolysis of zinc and the refining stages of lead also generate other metal rich solids. These are usually rich in a specific metal and are recycled to the appropriate production process. The ISF or direct smelting furnaces also are significant sources of solid slag. This slag has been subjected to high temperatures and generally contains low levels of leachable metals, consequently then may be used in construction. Solid residues also arise as the result of the treatment of liquid effluents. The main waste stream is gypsum waste ( $\text{CaSO}_4$ ) and metal hydroxides that are produced at the wastewater neutralisation plant. Some of these wastes are recycled to pyrometallurgical process to recover the metals. Dust or sludge from the treatment of gases are used as raw materials for the production of other metals such as Ge, Ga, In and As etc or can be returned to a smelter or into the leach circuit for the recovery of lead and zinc. Hg/Se residues arise at the pre-treatment of mercury or selenium streams from the gas cleaning stage. This solid waste stream amounts to approximately 40 - 120 t/y in a typical plant. Hg and Se can be recovered from these residues depending on the market demand for these metals (IPPC, 2001).

### 6.5.3 Emission

The emissions to air can escape the process either as stack emissions or as fugitive emissions depending on the age of the plant and the technology used. Stack emissions are normally monitored continuously or periodically and reported. The main emissions to air from zinc production are sulphur dioxide ( $\text{SO}_2$ ), other sulphur compounds and acid mists; oxides of nitrogen ( $\text{NO}_x$ ) and other nitrogen compounds; metals and their compounds; dust; VOC and dioxins (IPPC, 2001).

Main emissions to water are metals and their compounds and materials in suspension are the main pollutants emitted to water. The metals concerned are Zn, Cd, Pb, Hg, Se, Cu, Ni, As, Co and Cr. Other significant substances are fluorides, chlorides and sulphates (IPPC, 2001).

### 6.5.4 Smelting, primary zinc production in ecoinvent

No contiguous study on the zinc production is yet available, therefore this module is based in parts on values reported in Ayres et al. (2002), Xiao et al. (2003), IPPC (2001) and EEA (1999b).

The multi-output-process "smelting, primary zinc production" delivers the three co-products "zinc, primary, at regional storage", "cadmium sludge, from zinc electrolysis, at plant" and "leaching residues, indium rich, from zinc circuit, at smelter". The flow "zinc, ..." represents the European supply mix of primary zinc. The by-products "leaching residues, ..." and "zinc, ..." receive part of the burden and enter the primary production chain.

The module describes the production of primary SHG zinc used for galvanising in Europe, it does not consider secondary production, which accounts in Europe for 30% of the metal consumed (IPPC, 2001). The dataset is designed for the use of zinc in coating processes, and is not suitable for comparisons of products containing zinc in a high degree.

The meta-information to the multi-output process "smelting, primary zinc production" is given in Tab. 6.3. The layout of the modules with general flow information, remarks, sources, values and uncertainty information are shown in Fig. 6.12 (inputs) and Fig. 6.13 (outputs). The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one kg of zinc. The meta-information is compiled above in Tab. 6.3 in the beginning of this chapter.

**Consumption mix:** The consumption mix – i.e. the pattern of the production processes producing the zinc actually used for galvanising – is approximated with the production mix world-wide of 80% hydrometallurgical and 20% pyrometallurgical route. Low quality zinc (GOB) is mainly produced via the pyrometallurgical route without a final refining step (Graf & Schleining, 1997). According to IPPC (2001) 75% of the concentrates used in European production are imported, for which a distance of

5000 km transport by ship is assumed. Since Europe is the world leader in zinc production, no imports of refined zinc is assumed.

**Demand in materials and energy:** The input of zinc concentrate was taken from Ayres et al. (2002) to be in line with the material flow. Most other values are taken from Xiao et al. (2003), which inventoried one hydro- and one pyrometallurgical smelter in China. Electricity values had to be taken from IPPC (2001) since the detailed values presented in Xiao et al. (2003) could not be reproduced. Nevertheless they are shown together with the actually chosen values and the resulting mix in Tab. 6.24. Also the coal gas consumption reported by Xiao et al. (2003) seems to be too high compared to the values for natural gas reported by IPPC (2001). Since no information on the composition and heating value of the coal gas was available, the numbers for natural gas given by IPPC were taken in this study. There are indications that the total energy consumption indicated by IPPC (2001) is 27% and 31% of the values for the Hydro and the Pyro process reported in Xiao et al. (2003). However, since Xiao et al. (2003) does not characterise energy carrier and end energy uses sufficiently his results remain ambiguous and are not taken. No quantitative compilation of electricity production is available, therefore for pyrometallurgical processes the UCTE production mix was chosen as approximation (year 2000: nuclear 15%; hydro 4%; fossil 81%<sup>12</sup>). Since the electrolysis plants depend on cheap and readily available electricity, they often are located near hydropower dams often owned by the metallurgical enterprise. A compilation of electricity sources for the aluminium electrolysis is given in the part “Aluminium” of this report, where a specific dataset for the electricity production for the aluminium electrolysis is established. This dataset is chosen to approximate the zinc electrolysis.

**Emissions and disposal.** Wastewater is reflected by the direct emissions and the volume reported in Xiao et al. (2003) and IPPC (2001). An additional process covers solely the treatment process itself – infrastructure, mixing and pumping, without accounting for specific emissions from wastewater – as if the treated wastewater was unpolluted (Doka (2003)). Emissions are summed up in Tab. 6.25 (particulate emission to air) and Tab. 6.26 (other emissions to air and to water). The dioxin emissions are approximated with the reported emission factor of 50 µg-TEQ / t secondary zinc production in EC (2002).

**Tab. 6.26 Zinc: Emissions to water and air, except particulates & emissions from fuel combustion. Values correspond to the production of 1 t zinc with hydro- and pyrometallurgical processes. The values chosen in this study reflect the production split of 80% hydro- and 20% pyrometallurgical production. Some values are not reported by Xiao et al. (2003); for calculations they are approximated with zero.**

### 6.5.5 By-products and allocation

Of the many by-products that are jointly extracted with the zinc, indium and cadmium are modelled within this inventory. For these metals the zinc extraction is the dominant source for raw-material. In order to attribute a share of the environmental burden from the joint extraction, an allocation factor for the three products zinc, indium and cadmium has to be determined. In accordance with Althaus & Classen (2005) an allocation procedure by revenue is applied.

However, the allocation of the subprocesses indium-, cadmium and zinc-production is not evident to solve, since only the final commodity prices are known but no in-firm prices for the metal containing residues and for the raw zinc, on which the allocation would rely. Also no share of the products in total costs – gross sales method as proposed in Guinée et al. (2004) and Guinée et al. (2001) – is easy to estimate. The by-product allocation problem – the joint production of cadmium, indium and zinc – is reduced here by a subdivision of the sub-processes (according to Ekvall & Finnveden (2001)). The indium production from the leaching residues and the cadmium production from sludge respectively is treated in a distinct inventory. Hence it is the task to allocate the burdens between the zinc, the sludge and the leaching residues.

As a starting point for an estimation it is assumed, that the profit margin for the production of silver corresponds to the company's performance. Taking a performance value of 10%, the value of the indium containing residues corresponds consequently to 10% of the proceeds from the indium sales. Therefore 10 % of the indium price is taken to estimate the value of the residues. Since Cadmium is to

be regarded as contaminant that has to be isolated from the main product anyway, the cadmium containing sludge is regarded as burden free (cut-off).

### **By-product Cadmium in flue dust and purification precipitate**

There are mainly two different mechanisms how cadmium accumulates during the zinc production process. During roasting of the concentrate in the pyro-route the cadmium vaporises and accumulates in the flue dust that is collected in scrubbers or ESP. The second source is the cadmium sponge that is precipitated in the course of zinc solution purification prior to electrowinning. In both cases cadmium arises as unwanted element that has to be separated from the main product (hydro) and has to be retained for controlled handling (pyro) due to its toxicity. Due to the marginal position of the pyrometallurgical route, here only the cadmium sludge from zinc solution purification is modelled in this multi-output module.

With worldwide roughly 20'000 tons refined cadmium per year in 2006 (Tab. 3.1), the assumption that 72% of the cadmium refinery output originates from zinc extraction (see Reserves and Resources of Materials) would mean 13'500 tonnes that are direct by-products from the 10'000'000 tonnes primary zinc produced. In terms of mass this means that for every tonne of zinc extracted 1.5 kg cadmium is refined. This results in a back-calculated value of 0.29% Cd in a concentrate of 53% Zn content.

According to Fthenakis (2004) the cadmium content of the zinc concentrate is around 0.3% to 0.5%. This value is in the same order as the concentrate in the raw ore and implies that only in 20% of the co-extracted zinc is processed to ingots. The remaining 80% is supposed to be discarded, e.g. due to low concentration or missing markets.

The resulting cadmium sludge from zinc solution purification is assumed to consist of 50% water, 45% cemented cadmium and the rest of zinc dust. It is further processed in a cadmium plant, where the sludge is dewatered, oxidised and refined by means of electrowinning (see 6.6 Cadmium Production process and infrastructure).

Despite of Cadmium being a commodity traded at international exchanges, it has to be regarded as contaminant at the stage where it arises in the zinc metallurgy. According to the common allocation practice therefore no upstream burdens are to be attributed to the by-product cadmium (Guinée et al., 2004).

### **By-product Indium in purification solutions**

Indium is produced by a few companies only, all of which are in the zinc production. In those deposit where indium is present the concentration ranges between 10 and 100 ppm with 50 ppm being a common value of those operations recovering indium (e.g. Brunswick).

It is very uncertain to which amount secondary indium is recovered, because until 2002 it was not a technological issue due to favourable indium prices (Jansseune, 2003). The sky-rocketing prices and the connected ramping up of production facilities will have changed this picture by 2007 but no assured estimate is available in the open literature. Therefore, an amount of 30% secondary production is arbitrarily chosen to assess the coupling of indium production to the zinc extraction.

The trend for increasing indium recovery within the zinc industry is displayed in Fig. 6.11. Based on the last years, a ratio of 45 g refined Indium per tonne extracted zinc may be established assuming steady state stocks and optimal recovery measures. Under the assumption of correspondingly 70% indium from primary production, 3.4E-05 kg indium per kg zinc was chosen as joint production factor.

The indium containing intermediate product is a solution from wet-chemical purification processes. In the hydrometallurgical zinc recovery process at Akita mine (Dowa Mining Co, Ltd.), gallium and indium are recovered by three stages of ion exchange columns. The feed solution to the third ion exchange column contains the relative concentrations Ga: 0.26, In: 0.11, Zn: 1.0 g / l (Teramoto et al., 1993). A value of 0.1 g / l is chosen for further calculations.

Given an extraction yield of 60% and under the assumption, the indium contained in the residue amounts to 10% of the sales proceeds, a share of 0.09% of the burden is allocated to the indium containing by-product.

Fig. 6.11 Quotient of worldwide indium refinery production and zinc mine production as base for the assessment of the multi-output relation in ecoinvent USGS, 2006b). For explanations see in text above.

Tab. 6.27 By-products of primary zinc production: Composition, flows and value to derive the value-based allocation factors

| Metal                   | Process Yield | zinc concentrate (input) | cadmium sludge (output) | leaching residues, In (output) | Zinc, primary (output) | Value   |
|-------------------------|---------------|--------------------------|-------------------------|--------------------------------|------------------------|---------|

| Allocation by Value     |               |                          | -                       | 0.14%                          | 99.86%                 |         |

### Correction of resource flow allocation

Even though overall allocation is performed according to economic revenue, the resources are allocated by mass to the respective by-product to balance the mass flow. Since the concentrate required by this multi-output-process is allocated also by revenue, the therein contained resources are not correctly attributed and have to be corrected with a corrective exchange flow (Tab. 6.28).

**Tab. 6.28 Individual correction factors to allocate the resource depletion to the respective by-products in order to balance the mass flow.**

| correction from economic to per mass |    |          | according to economic allocation |             |           |
|--------------------------------------|----|----------|----------------------------------|-------------|-----------|

### 6.5.6 Data quality

Data uncertainty is derived using the Pedigree matrix as described in Frischknecht et al. (2004). Some of the less important emissions that are described in the literature as typical for lead, could not be covered in this inventory due to missing emission factors, viz. Ge, Ga In and Se into air and Se, Ni, Co and Cr to water. Also some salts –chlorides and sulphates – are not included due to missing data. Further investigations on these issues have been done to improve the quality of this dataset. However, for the purpose of a background database the quality is sufficient.

The inventory does not reflect the portion of secondary material in the zinc used. For specific conclusions further investigation has to be done. Further more, the choice of electricity mix bases on approximations that have to be improved with further investigations.

## 6. System Characterisation

## 6.6 Cadmium Production process and infrastructure

In hydrometallurgical zinc refining, cadmium is removed from the feed together with copper by reduction with zinc dust to give a metallic sludge. Similar cadmium sludge forms in the production of zinc sulfide pigments or zinc carbonate. These are the most important sources for cadmium refining today (Schulte-Schrepping & Piscator, 2002).

**Fig. 6.14 Sources and process routes for cadmium production. The most common production path is the electrolysis from processed cadmium sludge from hydrometallurgical Zinc operations (Schulte-Schrepping & Piscator, 2002), modelled in this study.**

Further secondary starting materials mentioned above may be added to potential primary raw materials without causing large alterations in the refining process. The different raw materials are dissolved in a solution.

Cadmium is extracted by oxidizing the enriched starting materials solutions. In order to oxidize the cadmium, either air is blown in or manganese dioxide is added. Cadmium is precipitated from the solution as a metal sponge by reduction with zinc dust. The precipitated sponge contains 90 % cadmium and only 2.5 % zinc.

Today, the largest amounts of cadmium are recovered electrolytically. The cadmium sponge is precipitated directly in the tank with the electrolytic acid. The anode consists of lead, which does not dissolve, whereas the cathode is aluminum sheet. The current yield is ca. 93 %; the energy consumption is 1250 kWh per tonne of cadmium cathode sheet deposited. Typical impurity levels in electrolytic cadmium sheet are 5 – 10 ppm Cu, 15 – 20 ppm Pb, 5 – 10 ppm Tl, and 5 ppm Zn.

### 6.6.1 Cadmium, primary, at regional storage in ecoinvent

This dataset gives only a rough estimate on the production of primary cadmium from leaching residues from hydrometallurgical zinc operations by means of electrolytic refining. It is mainly based on literature data (Schulte-Schrepping & Piscator, 2002) and is designed for the use of cadmium in electric devices, namely semiconductor applications such as CdTe-films.

The layout of the modules, general flow information, remarks, sources, values and uncertainty information are shown in

Fig. 6.15. The following paragraphs describe calculations, sources and assumptions chosen in this study. The functional unit of this process is one kg of refined cadmium sheet. Tab. 6.4 in the beginning of this chapter summarises the meta-information for this dataset.

**Precipitation.** The zinc dust used for cementation of the cadmium sponge is recovered later in the sludge of the electrolysis and will be returned into the zinc cycle. Therefore no account for zinc dust is done.

**Oxidation.** The oxidation of the sponge is often done with air, therefore no chemicals consumption is considered in this step. Also no additional heat for drying is assumed.

**Electrolysis.** The consumption of 1.25 kWh electricity per kg sheet is considered in this inventory as reported in Schulte-Schrepping & Piscator (2002). Taking copper electrowinning as approximation, 0.2 m<sup>3</sup> electrolyte per tonne is bled (drained) and purified for recycling into electrolytic refining (Davenport et al., 2002). It is assumed that all of this volume is replenished with fresh electrolyte (180 kg H<sub>2</sub>SO<sub>4</sub> per m<sup>3</sup>), since no process data on the purification of spent electrolyte are available.

Because of the lack of a complete and contiguous LCI study that treats the production of cadmium and the absence of problematic processes and auxiliaries employed, no emissions to air and water could be inventoried.

### 6.6.2 Data Quality

Data uncertainty is derived using the Pedigree matrix as described in Frischknecht et al. (2004). This dataset is comparably coarse since it disregards all but the most important environmental impacts attributable to this process. However, since cadmium is not used in applications as pure metal, but diluted in alloys or chemicals, this dataset is of sufficient quality. For the use of this inventory in applications where cadmium is a major constituent – e.g. in NiCd battery systems – the dataset must be complemented with additional specific emission factors and the secondary production process.

## 6.7 Indium Production Process and Infrastructure

Industrially, indium is produced mainly by recovering from by-products of zinc smelting such as fumes, flue dust, jarosite or leach solution (Kammer et al., 2006). These by-products contain small amounts of indium together with other accompanying elements. Therefore a complex hydrometallurgical process is required for isolating indium from impurities such as arsenic, zinc and cadmium. These processes highly depend on the composition given by the specific deposit.

Since the recovery processes are optimised to the main intended products – zinc, lead – the indium recovery is subject to quite a poor efficiency. Indium concentrates generally at two points in the hydrometallurgical zinc extraction process, while roasting the concentrate and in the neutral leach residue.

Jorgenson & George (2004) report that a traditionally low 30 % yield of available indium in treatable residues has been improved to nowadays 80%. Within the jarosite residues a maximum of 60% can be dissolved from the neutral leach residue, which leads to an estimated overall extraction efficiency of around 50% of the indium, i.e. 50% of the indium present in the ore is transferred to the pregnant solution.

If the indium content in the ore is back calculated based on process efficiencies and the indium refinery production and compared to the indium contained in the extracted lead-zinc ore with 50ppm In, it can be estimated that only 40% of the indium extracted is treated for recovery. Thus an overall yield of 19% may be estimated which corresponds to an overall yield of 20% indicated in Stevens (2007).

Generally, indium is recovered by removing impurities through various chemical purification methods such as acid and alkali leaching, solvent extraction, neutralization, sulphidising and cementation are combined to gain a high indium content solution. From this solution indium is either directly electro-won (e.g. Okamoto & Takebayashi, 1996) or precipitated with zinc as a refined sponge indium that is cast into anodes and electro-refined (Felix, 1996; Power Porto, 1990). To overcome undesirable chlorine gas generation while electrowinning, a two-compartment cell is required (Okamoto & Takebayashi, 1996).

### 6.7.1 Concentration of Indium in the solution

In this first step indium is concentrated from around 500 ppm in byproducts and 50 mg / l in a first leach stage to 30 g / l by hydrometallurgical means.

Generally indium containing byproducts arise in the extraction of zinc, lead and tin. The lead and tin metallurgy are quantitatively of minor importance in terms of mine production, although some big single operations are based on lead-zinc and tin deposits, e.g. Cominco at Trail, Canada. Among the indium producers in tin circuits, Capper Pass in Hull, U. K. is mentioned (Alfantazi & Moskalyk, 2003; Felix, 1996; Power Porto, 1990). However, this operation has been – last owned by Rio Tinto Zinc Ltd. – closed down in 1991 and decommissioned. Since then the tin circuits are of minor importance as source for indium bearing raw materials.

In technical literature quite a few different purification processes are described that follow a row of leaching, neutralisation and precipitation stages. However, the more recent patent literature gives strong indications that solvent extraction (SX) techniques are favoured as e.g. proposed by Tomii & Tsuchida (1981) and studied by Power Porto (1990) and Fortes et al. (2003). This development is linked to a shift in the zinc extraction technology from pyrolytical processes to hydrometallurgical processes, where indium accumulates in the leach solution. In a review article Paiva (2001) states, that commercial grade indium is industrially produced using leaching, cementation and electrowinning technologies. SX is often used to recover indium from leach residues. More recent work confirms this tendency and indicates the introduction of more specific ion exchange and extraction resins (Liu et al., 2006; Zhou & Ruan, 2006).

Based on the above mentioned sources it can be concluded that most of the indium produced today is won in hydrometallurgical zinc operations like the Akita refinery in Akita, JP or the Zhouzhou smelter in Hunan Province, China, Cominco's Trail operation (30 tonnes per year<sup>13</sup>) or Falconbridge's Kidd Creek Refinery, Canada. These operations process ores from close-by mines and indium bearing intermediate products, prompt scrap and post consumer scrap.

A typical process scheme for this type of operations is given in Fig. 6.16 on the example of the Kidd Creek refinery. The process is similar to the descriptions given in Kudo & Maruyama (2001) and Power Porto (1990).

Fig. 6.16 Process scheme of Falconbridge's Kidd Creek refinery<sup>14</sup>

The leach solution which carries indium has usually a concentration of 120 ppm in Zinc residue (Akita, Alfantazi & Moskalyk, 2003), 50-70 mg / L after first leaching (Akita, Felix, 1996) 690 mg / L (typical zinc plant after concentration, Fortes et al., 2003), 200 mg / L (Laboratory setting, Liu et al., 2006, 0.4% (in secondary oxide, 0.68% after preleaching Felix, 1996), 2.7% chloride slag (copper pass, Felix, 1996). Stevens (2007) indicates a range of 300-500 ppm for high indium concentrates.

This solution is concentrated either by SX or a row of neutralisation-precipitation steps to ca. 1 g / L (Power Porto, 1990), or 2 g / L (Akita; Felix, 1996). From this solution sponge indium is precipitated either on aluminium sheets or with zinc powder. The resulting sponge is cast to raw indium anodes with a purity of 95-99.5 %.

As Tomii & Tsuchida (1981) put forward, a main challenge of the neutralisation process is the removal of accompanying contaminants, therefore this quite unspecific procedure is highly complicated, costly and does not yield the purity required for subsequent refining to 5N (five nines = 99.999%) quality. Within the different concentration techniques SX today is regarded as one of the most promising separation operations (Paiva, 2001).

<sup>13</sup> In 2005, <http://www.teckcominco.com/operations/trail/production.htm>, accessed in april 2007

<sup>14</sup> <http://www.xstrata.com/>, accessed in april 2007

However, because of the presence of ions with similar extraction tendency as indium, it is difficult to prepare high purity indium (>4N) only by electrowinning unless several combinations of purification methods are applied (Zhou & Ruan, 2006).

Therefore a sequence of (i) solvent extraction (ii) cementation with zinc powder (iii) anode casting is considered to be the most appropriate process for gaining raw indium that meets the requirements for further refining to over 5N quality. This process corresponds to the study set-up in Power Porto (1990) that is shown in Fig. 6.17.

Fig. 6.17 Study set-up of a semi industrial extraction facility by Power Porto (1990) that reflects an up-to-date solvent extraction process scheme. Process covers solvent extraction and cementation; the resulting cementate ("In-Zementat") is cast further into anodes, which is not depicted in this figure.

## 6.7.2 Refining of Raw Indium

There are basically three possibilities described for refining raw sponge indium (99.5%) to the required 5N purity: Vacuum refining, electrorefining zone refining and electrowinning or a combination of all of these. Kammer et al. (2006) additionally mention distillation of  $\text{InCl}_3$  and vacuum distillation. The main challenge is to remove the accompanying contaminants that have a negative effect on the properties of the semiconductor made from indium. Namely thallium and cadmium have detrimental effects on the semiconducting properties.

Purification of metals by vacuum refining is widely practiced. Generally vacuum refining is employed after the electrolytic step to further reduce the level of volatile impurities in the indium metal. Indium metal has low melting point and high boiling point. Therefore, it is possible to remove the impurity metals with high vapour pressure by distilling indium metal at relatively low temperature under vac-

uum. The impurity metals, which are not well removed by chemical methods, are easily removed by vacuum refining at relatively low temperatures (Lee & Sohn, 2003).

### 6.7.3 Indium production in ecoinvent

The module describes the primary production of indium metal (99.999%, 5N purity) on a European average. It is based on the respective flow from the multi-output module "smelting, primary zinc production". Meta-information for this dataset are given in Tab. 6.5, an overview over the inventory is given in Fig. 6.18

Due to the strategic importance of the material and because of the heterogeneous raw materials, no contiguous information on the most common recovery processes are available for LCI modelling. However, there exist many procedures common with the solvent extraction / electrowinning process used in copper production. There also pregnant leach solution is subjected to a solvent-solvent extraction. Based on the process descriptions above, following general steps are covered in this inventory:

- Leaching and solvent extraction with D2EHPA
- Cementation with zinc powder and anode casting
- Electrefining
- Vacuum distillation

#### Leaching and solvent extraction (SX)

The inventory bases on the leaching residues from hydrometallurgical zinc extraction as raw materials. Davenport et al. (2002) states that in the case of SX in copper production 35 g Cu / L are required for electrowinning. SX has to yield this concentration starting from leach solutions not richer than 1 - 6 g / L. This concentration factor of around ten times is comparable with the SX of indium, where a solution of 50 – 200 mg / L is concentrated to 1 to 2 g / l.

In this study it is assumed that the lower concentration level in the case of solvent extraction of indium leads to a proportional increase of throughput compared to SX of copper. The leach solution of indium is 20 to 30 times less concentrated than in the copper extraction. It is assumed in this study, that the required accumulation of indium requires consequently 20 to 30 times the volume put through. Hence the specific emissions as well as energy and material consumption documented for the solvent extraction of copper are multiplied by 25 and are taken as approximation for the SX of indium. The values for electricity consumption for pumping, mixing, etc. as well as the "crud" generation (solid particles associated with oil/water dispersions that are disposed of) are taken from Krauss et al. (1999). Direct emissions were estimated based on reported yearly air emissions of an U.S. SX/EW copper operation in Arizona (ADEQ, 2006) and the reported copper output of the facility<sup>15</sup>.

#### Cementation and anode casting

Crude indium is formed by the precipitation of a sponge. Here, it is assumed that the sponge contains 20%wt moisture and is dried prior to anode casting. Drying is assumed to be effected in a spray dryer used in ceramic industry (38kW at 250 kg per hour Timokhova (2002), Melting is assessed using the heat of fusion and assuming a system efficiency of 70%.

### Electrorefining

No information on electrorefining of indium was available. However, this process – where the anode dissolves anodically – usually ranges between 0.2 to 0.5 kWh per kg. In this inventory a value as required in copper refining is chosen. In Davenport et al. (2002, Tab 16.4) for electrorefining of copper a range of 0.25 to 0.35 kWh / kg is given. Taking the upper value, an electricity consumption of 0.35 kWh per kg indium cathode sheet is assumed.

Belsky et al. (1980) state a current density of 0.015 to 0.03 A / cm<sup>2</sup> (150 to 300 A / m<sup>2</sup>) for the electrorefining of indium, which is comparable to copper (200 to 300 A / m<sup>2</sup>). Zhou et al. (2005) determine optimal conditions of 0.2-0.3 V bath voltage but at lower current densities of 50-80 A / m<sup>2</sup>.

In Davenport et al. (2002) it is stated that 0.1 to 0.2 m<sup>3</sup> electrolyte is bled per tonne of copper, i.e. recirculated for purification. In Zhou et al. (2005) the electrolyte is a low concentration solution of sulphuric acid. We assume a value of 0.15 kg 25% H<sub>2</sub>SO<sub>4</sub> per kg indium refined.

### Vacuum refining

A continuous process is described in McNamara et al. (1989) on behalf of Indium Corporation of America Inc. In the proposed installation liquid indium is heated under vacuum (10<sup>-7</sup> to 10<sup>-8</sup> torr) to 1'400 °C in order to volatilise remaining impurities. The original patent by Belsky et al. (1980) remains less specific but claims the process duration of two heating phases of 1-5 h at 850-940°C followed by 0.5-2 h at 950-1100°C. The long duration of this refining step is also confirmed by Lee & Sohn (2003) who found slow evaporation rates. In this study we assume that a RF induction heated Vacuum furnace is employed that uses 0.5 kW per kg load. This assumption corresponds to a batch of 30 kg indium that is heated for 4 hours in a 15kW furnace as often used in lab-scale. Commercial furnaces<sup>16</sup> exhibit energy supply from 36 kW (0.01 m<sup>3</sup> volume) to 90 kW (0.127 m<sup>3</sup> volume). Assuming that one third of the heated volume can catch the indium load (7.3 g / cm<sup>3</sup>) a somewhat higher span of 0.5 – 0.3 kW per kg batch size results. Inductotherm Corp. reports 0.15 kW per kg for its Acutrac (R) furnace<sup>17</sup>. However, bearing in mind that the metal is very costly and no large batch sizes are supposed to be processed, the upper value of this span is justified.

Additional power consumption for vacuum preparation is disregarded due to a lack of reliable sources and because this particular process is expected to be of minor importance compared to the overall impacts. Also the inert gas atmosphere is supposed to be of minor importance for the environmental impacts and is therefore not inventoried.

### Transport and Infrastructure

The indium metal is assumed to be transported by lorry to and from the airport (250 km each), by plane over 5'000 km to Europe. Additional weight due to packaging is accounted for with additional 50%.

The infrastructure is estimated based on the module "chemical plant, organics", that has a built area of about 4.2 ha and an average output of 50'000 t/a (Althaus et al., 2003).

#### **6.7.4 Data Quality Considerations**

The production process is rather new and not much is known from public sources about quantitative process measures. Therefore the data has been established based on theoretical reasoning and rough assumptions, extrapolating the data from copper refining. Except for the sub-process of solvent extraction which employs organic extraction solution and emits VOC and H<sub>2</sub>SO<sub>4</sub> mist, no direct emissions from other sub-processes have been considered. Infrastructure has been approximated with the related technology of chemical plants. The uncertainty of the used environmental flows has been calculated with the pedigree approach. The data does comply with the demands for the use in electronic devices. This dataset is not to be used when indium is a substantial part of the system modelled (e.g. for comparisons of special solder paste).

## Part IX

# Gold and Silver

Data v2.1 (2009)

Authors: Mischa Classen, EMPA Dübendorf  
Matthias Tuchschnid, ESU-services Ltd.  
Mireille Faist Emmenegger, ESU-services Ltd.  
Wolfram Scharnhorst, EMPA Dübendorf

Review: Roberto Dones, PSI, Villigen

Classen M., Althaus H.-J., Blaser S., Tuchschnid M., Jungbluth N., Doka G., Faist Emmenegger M. and Scharnhorst W. (2009) Life Cycle Inventories of Metals. Final report ecoinvent data v2.1, No 10. EMPA Dübendorf, Swiss Centre for Life Cycle Inventories, Dübendorf, CH, Online-Version under: [www.ecoinvent.ch](http://www.ecoinvent.ch).

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1

## Comments on version 2.1

This part corresponds to version the part in version 2.0 without changes.

## Comments on this part

The Swiss Federal Office for the Environment (FOEN) commissioned Empa in 2005 to identify the datasets that have to be improved in order to improve the overall quality and applicability of metals inventories in the metal processing and electronic industry. Based on that preparatory study Gold and Silver were identified as widely applied metals with potentially high impact and therefore of high relevance.

## Summary

This part documents the inventories for primary and secondary silver and gold, respectively, as well as the production of copper telluride cement, which is a by-product of the treatment of copper anode slimes in order to recover silver. The inventories for primary gold are compiled country specifically according to the environmental reports of the world leading gold producers. These inventories also cover the production of silver from auriferous ores in a multi-output module. The rest of the primary silver production is reflected by the processing of silver bearing by-products of lead / zinc (Parkes crust) and copper (anode slimes) production. Secondary gold and silver production is reflected by the recovery processes in complex integrated smelters (Boliden, SE).

# 1 Introduction

This life cycle inventory (LCI) of gold and silver is meant to be used as background data sets for the preparation of life cycle assessments (LCA) of technical products such as electronic components. This LCI includes data sets of gold mining and refining in Australia, Canada, Chile, Peru, Papua New Guinea, South Africa, Sweden, Tanzania and the USA, as well as of the gold supply to Europe. It also includes data sets of silver as a by-product of gold production in Chile, Peru, Papua New Guinea and Sweden.

Data in this report are based mostly on environmental reports of large multinational companies. However, it must be assumed that these sources represent rather the best practices for gold mining. Various NGOs like Berne Declaration, Greenpeace<sup>1</sup> etc. report on severe impacts of gold mining on environment, local communities or human rights concerning projects or mines of important companies like Barrick Gold and Newmont Mining, the two largest gold companies of the world today. Controversial issues are for example a mine project in Chile involving relocating/destroying of three glaciers in the Andes which are of crucial importance to the Pascua Lama Highlands, or the development of a mine in Nevada, USA in the Western Shoshone Lands, which is expected to have a negative effect on the region's scarce water resources and to destroy Shoshone sacred places. The nodirtygold campaign<sup>2</sup> denounces among others the problem of tailings dam failures which release large amounts of cyanide-laden tailings in rivers. Such impacts of the gold mining are very difficult to quantify and include in LCI due lacking of data and also because of the punctual character of the events. Therefore it must be assumed that the environmental impacts of gold mining are rather underestimated in the following data sets, which consider only regular operation.

## 2 Reserves and Resources of Materials

### 2.1 Gold

#### 2.1.1 Gold from primary resources

“Gold abundance in the Earth’s crust is 0.002 per 10<sup>6</sup> atoms of silicon. Gold average economic abundance in the ore is today in the range of 0.1 to 0.2 oz/ton or 3.42-6.84 gram per ton of ore, but also deposits with a tenth of those values, are exploited.” (Gasparrini, 1993)

In the last years gold was produced in following countries:

**Tab. 2.1: Annual share of gold mine production<sup>3</sup>.**

The total volume of gold production is rather stable. However, substantial changes occurred by the country. South Africa’s production diminished between 2000 and 2004, whereas production in Russia, China and Peru increased considerably.

This life cycle inventory is based on data from Australia, Canada, Chile, Peru, Papua New Guinea, South Africa, Sweden, Tanzania and the United States of America. The data set „gold primary, at refinery“ takes into account the average production shares 2000-2004 of these countries (Tab. 2.2). Production in African countries is approximated by South African and Tanzanian production, production in South and Central America by Chilean and Peruvian production, production in Asia (incl. Middle East) and Pacific by production in Papua New Guinea, and production in Europe by Swedish production. The production from Russia / former USSR is approximated with Canadian production, due to similar geographical and meteorological conditions.

### 2.1.2 Gold from secondary resources

Among other precious metals, such as silver, palladium, platinum, etc., gold is contained in varying amounts in metallic scrap of any kind. Depending on the application, for instance printed wiring board assemblies may contain between 0.03 wt% (Goosey & Kellner, 2002) and 0.089 wt% (Motorola, 2005). Other authors report gold contents ranging from 0.035 wt% up to 0.18 wt% (Zhang et al., 2000). Other sources of secondary gold are: scrap jewellery, dental applications, plated rejected components, porcelain scrap, and mirrors (George, 2006; Syed, 2006).

In the U.S. the production of secondary gold has increased from 16.1 tonnes in 1964 to 45.0 tonnes in 2004 and thus accounts for about 14.8 % of the total gold production (Geoffroy & Cardarelli, 2005; George, 2006). Due to the scarcity of the metal and because of the drastically increased demand, the price of gold (and secondary gold) has risen dramatically since the late 1970ies.

Fig. 1 Value of gold (adapted from George (2006)).

Key sources for the refinement of secondary gold, however, are new and old metallic scrap. In 2000 it was estimated that about 280 tonnes of gold were present in electronic goods (Holliday & Goodman, 2002). Gold can be extracted from the scrap in a number of subsequent steps (depending on the required degree of purity) with a purity between 90.0 % (Doré) and 99.99 % (Boliden Contech A.B., 1995). Again, depending on the intended application of the final product, the recovered gold is either added as bullion or higher grade secondary gold to primary gold. Along with the extraction of gold

from new and old electronic scrap, typically silver, palladium and (in case) selenium are co-extracted (Boliden, 2000; Boliden, 2002a; Boliden Contech A.B., 1995).

## 2.2 Silver

The extraction of silver from true silver ores – in which silver is practically the only valuable metal – is by far not the biggest source for supply. Depending on the price of silver, it can be cost-effective to process materials containing 0.01 % (100 ppm) silver, or even less. The most important primary sources of silver are traditionally argentiferous lead and lead-zinc ores that are widely distributed. They constitute the most important fraction of the mine production. However, since the mine production of lead declined in the last years, these deposits became less important for the worldwide supply. The separation and recovery of silver during lead production is profitable even for a silver content of a few ppm. Argentiferous copper ores, which sometimes also contain nickel and cobalt, satisfy another important share of the world silver demand. Even very low contents of silver can be recovered profitably from copper ores, since almost all the copper is electrorefined, and the silver remains in the anode slimes. The largest argentiferous copper reserves in the world are in Canada (Sudbury, Ontario, Noranda-Rouyn, Quebec). Extraction of silver from gold ores is carried out mainly in the Republic of South Africa, and also in Canada, Alaska, and Sweden. The quantity obtained from these deposits is around 10-20% of the world mine production. Silver-containing tin deposits are concentrated in Bolivia (Cerro de Pasco, Potosi) but also occur in Burma and Argentina. Silver produced from tin ores amounts to only 2 % of world silver production. (Renner et al., 2002b).

### 2.2.1 Silver as by-product of lead/zinc, copper and gold production

Most of the world silver is produced as by-product from lead/zinc, copper and gold bearing deposits. The share of the different ore deposits that constitute the world mine production changes over the years (Tab. 2.3). Recently, the Silver Institute (2002, p. 26) estimates the breakdown by ore type as follows: 25 % silver ores, 15% gold ores, 24 % copper ores, 35% lead, zinc, and lead-zinc ores and 1% other ores (Butterman & Hilliard, 2004, JMB, 2002) Nigel H Maund estimated the supply in 2004 as follows<sup>4</sup>: Lead - Zinc deposits (mostly Mexico and Cannington, and smaller Chinese contributions) 31%; Copper deposits (Kupferschiefer of Poland and porphyry copper mines) 25%; Gold deposits (in particular Carlin type) 14% Primary silver deposits (in particular "Idaho type") 28%.

This LCI corresponds to the available data from Klapwijk ((2006, p.87)) as shown in Tab. 2.4, that specifies the share of the origin countries for the data set „ silver mix, from combined gold / silver production, at refinery“.

## 2.2.2 Silver from old scrap

According to the Silver Institute 21% of the silver demand was satisfied from old scrap (Klapwijk et al., 2006) (as Secondary in Tab. 2.3).

## 2.3 Allocation for Metals

Metal prices are used as the allocation parameter for polymetallic mines. Prices in USD of copper, lead, zinc, gold and silver stem from Boliden for the year of 1996 and 2001, the prices for 2005 are from USGS (2006). The prices per tonne in the yearly average 2004-2006 are compiled from Kelly & Matos (2007) through 2004 and the respective 2007 mineral commodity summaries from USGS (2006) for values after 2004. These prices have been used in this project for the allocation of different metals.

<sup>5</sup> “Silver – An Economic Geologist Perspective”, [http://www.gold-eagle.com/editorials\\_04/nmaund072004.html](http://www.gold-eagle.com/editorials_04/nmaund072004.html)

Prices were relatively stable between 1996 and 2001, whereas a strong demand in the years 2005 to 2006 lead to a sharp increase in 2006 (see Tab. 2.5). Relative shares remained about constant.

**Tab. 2.5: Price of gold, silver, copper, lead and zinc 1996, 2001, 2005 and the average prices 2004-2006, used in this project (sources see text).**

## 3 Characterisation of the materials

For gold and silver the term precious metals is used because of their rarity and corrosion resistance. Gold and silver are often mined together in polymetallic mines.

### 3.1 Gold

Apart from copper, Gold is the only metallic element with a colour different from a grey tone. It is a soft yellow metal with a moderately high melting point (1064°C) and a high electrical and thermal conductivity exceeded only among the elements by silver and copper. It is the most malleable and ductile of the metals. One ounce of gold can be beaten in to foil some 300 square feet in area. Tab. 3.1 displays some physical properties of the element gold.

**Tab. 3.1** Some physical properties of gold (Renner et al., 2002a).

| Property                      | Value                                  |
|-------------------------------|----------------------------------------|
| Melting Point                 | 1064.43°C                              |
| Boiling Point                 | 2808°C                                 |
| Density at 20°C               | 19.32 g/cm <sup>3</sup>                |
| Density at 1065°C             | 17.32 g/cm <sup>3</sup>                |
| Vapor pressure at 1064°C      | 0.002 Pa                               |
| Atomic volume at 20°C         | 10.21 cm <sup>3</sup> /mol             |
| Electrical resistivity at 0°C | 2.06×10 <sup>-6</sup> Ω cm             |
| Thermal conductivity at 0°C   | 3.14 Wcm <sup>-1</sup> K <sup>-1</sup> |
| Specific heat                 | 0.138 Jg <sup>-1</sup> K <sup>-1</sup> |
| Enthalpy of fusion            | 12.77 kJ/mol                           |
| Enthalpy of vaporization      | 324.4 kJ/mol                           |
| Tensile strength              | 127.5 N/mm <sup>2</sup>                |

### 3.2 Silver

“Silver has a moderately high melting point (961.9°C) and the highest electrical and thermal conductivity of all metals. When in the metallic form, silver is unaffected by water or oxygen, but is altered by ozone with the formation of silver oxide, and by sulphur and other sulphur compounds with the formation of silver sulphide” (Gasparrini, 1993). Tab. 3.2 summarises some physical properties of elemental silver.

**Tab. 3.2** Some physical properties of silver (Renner et al., 2002b).

| Physical Property               | Value                                   |
|---------------------------------|-----------------------------------------|
| Melting point                   | 961.9 °C                                |
| Boiling point                   | 2212 °C                                 |
| Specific heat capacity at 25 °C | 0.23 J kg <sup>-1</sup> K <sup>-1</sup> |
| Thermal conductivity            | 418 W m <sup>-1</sup> K <sup>-1</sup>   |
| Vapor pressure at 1030 °C       | 1.33 Pa                                 |
| Density at 20 °C                | 10.49 g/cm <sup>3</sup>                 |
| Density of liquid at mp         | 9.35 g/cm <sup>3</sup>                  |
| Brinell hardness                | 26                                      |
| Modulus of elasticity           | 82 000 MPa                              |
| Tensile strength                | 140 MPa                                 |
| Resistivity at 0 °C             | 1.465 Ωcm                               |

## 4 Use / Application of Material

Gold is used mainly for jewellery, electronics and other industrial and decorative appliance (Tab. 4.1). In electric/electronic devices, it is mostly used as connector or as solder paste (Goosey & Kellner, 2002). The latter one is typically a gold alloy incorporating Si (98%Au, 2%Si), Ge (87.5%Au, 12.5%Ge), In (82%Au, 18%In) or Sn (80%Au, 20%Sn). The principal users of silver are industrial applications, photography and jewellery (Fig. 4.1).

Tab. 4.1 World Gold demand in different application fields (World Gold Council<sup>6</sup>).

## 5 System Characterisation

The production of silver is heavily interlaced with the production of other metals, namely lead and zinc, copper and gold. This is taken into account by establishing a complex LCI model (Fig. 5.1, for supply mix see chapter 5.6 *Silver, at regional storage*). However, not every source contributing to the worldwide production of gold and silver could be evaluated in ecoinvent version 2.0.

Due to a considerable lack of systematic information on processes in the artisanal mining of gold, no inventory on these processes could be established. The production of silver as main product – which accounts for 22% of the world supply – has been disregarded in this study for two reasons: first, a coverage of 78% seems fair enough to represent silver. Second, the production of silver as main-product occurs with the same technologies as the production of silver as by-product and thus can be approximated by these datasets. An overview over the system boundaries chosen for the inventories in this chapter is given in Fig. 5.2.

Fig. 5.1 General overview of Silver and Gold production.

Fig. 5.2 System lay-out in ecoinvent data v2.0. Boxes with rounded edges indicate reference flows from multi-output processes.

## **5.1 Production of gold and silver from auriferous ores**

### **5.1.1 Gold and silver mining**

The description of gold production is based on Newmont (2004).

#### **Exploration**

The gold mining process begins with geologists discovering a deposit. After finding indications of gold, drill rigs are used to obtain samples from below the surface. These samples are analyzed for their gold content. If there is enough gold in the deposit to be produced economically, a mine is permitted and developed, if environmental regulations are fulfilled.

#### **Open Pit Mining**

The ore is mined in four steps: drilling, blasting, loading and hauling. In the case of a surface mine, a pattern of holes is drilled in the pit and filled with explosives. The explosives are detonated in order to break up the ground so large shovels or front-end loaders can load it into haul trucks.

#### **Underground Mining**

Some ore bodies are more economically mined underground. In this case, a tunnel called an adit or a shaft is dug into the earth. Sort tunnels leading from the adit or shaft, called stopes, are dug to access the ore. The surface containing the ore, called a face, is drilled and loaded with explosives. Following blasting, the broken ore is loaded onto electric trucks and taken to the surface. Once mining is completed in a particular stope, it is backfilled with a cement compound.

#### **Ore and Waste Haulage**

The haul trucks transport the ore to various areas for processing. The grade and type of ore determine the processing method used. Higher-grade ores are taken to a mill. Lower grade ores are taken to leach pads. Some ores may be stockpiled for later processing.

#### **Heap leaching**

##### *Heap leaching*

The ore is crushed or placed directly on lined leach pads where a dilute cyanide solution is applied to the surface of the heap. The solution percolates down through the ore, where it leaches the gold and flows to a central collection location. The solution is recovered in this closed system. The pregnant leach solution is fed to electrowinning cells and undergoes the same steps as described below from Electro-winning.

#### **Ore Processing**

##### *Milling*

The ore is fed into a series of grinding mills where steel balls grind the ore to a fine slurry or powder.

##### *Oxidization and leaching*

Some types of ore require further processing before gold is recovered. In this case, the slurry is pressure-oxidized in an autoclave before going to the leaching tanks or a dry powder is fed through a roaster in which it is oxidized using heat before being sent to the leaching tanks as a slurry. The slurry is thickened and runs through a series of leaching tanks. The gold in the slurry adheres to carbon in the tanks.

##### *Stripping*

The carbon is then moved into a stripping vessel where the gold is removed from the carbon by pumping a hot caustic solution through the carbon. The carbon is later recycled.

*Electro-winning*

The gold-bearing solution is pumped through electro-winning cells or through a zinc precipitation circuit where the gold is recovered from the solution.

*Smelting*

The gold is then melted in a furnace at about 1'064°C and poured into moulds, creating doré bars. Doré bars are unrefined gold bullion bars containing between 60% and 95% gold.

**Refining**

The bars are sent to a refinery for further processing into pure gold.

**5.1.2 Gold and silver production, Sweden (SE)**

The following data on gold and silver origin from the reports of the Swedish company Boliden (2006a), that operates mines and smelters in Sweden, Finland, Norway, Ireland and the Netherlands (copper, zinc, lead, gold and silver production). This LCI includes the data of the Swedish mines Aitik, Boliden and Garpenberg, which produce gold, silver and other metals.

**Mining infrastructure**

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. The open pit mine “Aitik” produces the large part the ore. Therefore data for buildings and machines are based on the (generic) data set “non-ferrous metal, mine, surface” (and not “non-ferrous metal, mine, surface underground”). For details about infrastructure in mining, see the corresponding section of this report. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (Tab. 5.1). The lifetime of mines is assumed to be 50 years.

**Tab. 5.1: Quantity of machinery as well as surface and volume of buildings for a “non-ferrous metal mine, surface”, Source: see corresponding section in this report**

| Dataset                                          | Unit           | Quantity per mine (lifetime 50y) |
|--------------------------------------------------|----------------|----------------------------------|
| <i>infrastructure, mine, surface</i>             |                |                                  |
| building, multi-storey                           | m <sup>3</sup> | 2.75E+5                          |
| building, hall                                   | m <sup>2</sup> | 1.25E+4                          |
| industrial machine, heavy, unspecified, at plant | kg             | 8.50E+5                          |
| conveyor belt, at plant                          | m              | 6.00E+2                          |

Land use is based on the aggregated figures from the environmental report (Tab. 5.2). Not the entire area of the mine is in active use at one time; the value in Tab. 5.2 is assumed to be the average share of the mine area in use (see line “Disturbed area in active use”). The total area is occupied during an average of about 11 years according to the following formula:

$$\frac{\text{Disturbed area in active use}}{\text{Area disturbed during life of mine}} * \text{lifetime of mine} = \frac{4.65 * 10^7}{1.98 * 10^8} * 50y = 11.6y$$
, the occupation of the mine is calculated as Disturbed area in active use \* 50y = Occupation, mineral extraction site

Tab. 5.2 Land use of the Aitik, Boliden Area and Garpenberg Mines in 2005 (Boliden, 2006d)

## Mining

The energy and water requirements as well as the emissions are allocated to the different metals on the basis of their economic value calculated with the prices shown in Tab. 2.5. Tab 5.4 summarizes the concentrate production (expressed in metal quantity) of the considered plants for the year 2005.

**Tab 5.4: Production (quantity of metals) in year 2005 of the mines Aitik, Bolden and Garpenberg mines (Boliden, 2006a)**

| Production                       |           | Aitik    | Boliden Area | Garpenberg | Sweden          |                                  |

| Recovery rate of metals from ore |           |          |              |            | <b>90%</b>      | Assumption, based on global data |

The recovery rate (proportion of valuable material physically recovered in the processing of ore<sup>8</sup>) is taken into account in order to define the resource extraction. It is estimated 90% on the basis of global data. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for Sweden is calculated with the quantity of ore milled and the corresponding production rate.

The turnover of the production sites (Table 5.5) is calculated with the metal quantity multiplied with the prices (2005) in Tab. 2.5. The share in turnover is used as allocation factor for the respective metal.

**Table 5.5: Calculated turnover (prices 2005) and derived allocation factors for the Swedish mines**

Energy and water requirements as well as emissions of the considered mines are summed up in Table 5.6. Water emissions are assumed to be emitted to rivers.

<sup>8</sup> The recovery rate is generally stated as a percentage of the material recovered compared to the total material originally present ([Barrick, 2007 #2767]).

**Table 5.6: Total energy, material requirements, and emissions of the Swedish multi-metal mines in 2005 (Boliden, 2006a); n.a. = not available**

The unit process raw data of metal mining in Sweden are summarized in Tab. 5.7 and Tab. 5.8. Cyanide consumption is estimated with the average of US-Data from Barrick (2006b) and Newmont (2005b) (scaled by the produced gold), other material requirements are estimated with Australian data (scaled by the produced gold and silver). Material requirements are estimated only for the gold and silver production. Since the module “blasting” does not include the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive). Transport of materials is calculated on the base of standard distances (Frischknecht et al., 2004). Data about tailings disposal is approximated with data from Papua New Guinea.

## Refining

The total production in 2005 of the smelter in Rönnskär amounted to 223'400 tonnes of copper, 27'000 tonnes of lead, 35'000 tonnes of zinc, 430 tonnes of silver and 17 tonnes of gold. A high share of the production is recycled metal, e.g. 74% for gold. Since the production of secondary gold and silver from scrap is investigated in a dedicated chapter of this report, only material requirement and emissions from the treatment of primary material is considered (see Tab. 5.10). Gold and Silver are treated in the PGM plant in Rönnskär, the other metals undergo other treatments.

Tab. 5.9 Metal production volume 2005 from primary material (Boliden, 2006b)

| Production              |    | from Scrap |     | from Mines   | Remark:                                                                                  |
|-------------------------|----|------------|-----|--------------|------------------------------------------------------------------------------------------|
| concentrate from Mines  | kg |            |     | 6.47E+08 82% | from Boliden (2005)                                                                      |
| Secondary Raw Materials | kg | 1.41E+08   | 18% |              | from Boliden (2005)                                                                      |
| contained lead          | kg | n.a.       |     | 2.22E+07     | calculated from output with share of concentrate input, in LCI: lead, at beneficiation   |
| contained copper        | kg | n.a.       |     | 1.83E+08     | calculated from output with share of concentrate input, in LCI: copper, at beneficiation |
| contained Zinc          | kg | n.a.       |     | 2.87E+07     | calculated from output with share of concentrate input, in LCI: zinc, at beneficiation   |
| contained gold          | kg | 1.25E+04   |     | 4.47E+03     | from Boliden(2005), in LCI: gold, at beneficiation                                       |
| contained silver        | kg | 2.04E+05   |     | 2.26E+05     | from Boliden (2005), in LCI: silver, at beneficiation                                    |

The allocation on the basis of the revenue (estimated with the prices of Tab. 2.5) results in 54% of the requirements and emissions attributed to gold and 46% attributed to silver for the PM-plant (Precious metal plant). The allocation for the refining of the other metals results in 6% attributed to zinc, 91% to copper and 3% to lead (see Tab. 5.10).

Tab. 5.10: Metal production volume in 2005, calculated turnover and shares in turnover of the different products in the Rönnskär Smelter (Boliden, 2006b). The revenue is calculated on the basis of the metal prices in Tab. 2.5 (average from the years 2004-2006). The PM-Plant is a sub process of the refinery, dedicated to the refinement of gold and silver.

| Allocation of metals |    | refining metals | Calc. Turnover  |             |                                                                  |
|----------------------|----|-----------------|-----------------|-------------|------------------------------------------------------------------|
| Production Gold      | kg | 4.47E+03        | 7.01E+07        | 6.8%        | refining gold-silver (PM-plant) 53.6% Price per kg: 15682.1 US\$ |
| Production Silver    | kg | 2.26E+05        | 6.07E+07        | 5.9%        | 46.4% Price per kg: 268.7 US\$                                   |
| Production Zinc      | kg | 2.87E+07        | 5.39E+07        | 5.2%        | refining, copper-zinc-lead 6.0% Price per kg: 1.9 US\$           |
| Production Copper    | kg | 1.83E+08        | 8.21E+08        | 79.6%       | 91.2% Price per kg: 4.5 US\$                                     |
| Production Lead      | kg | 2.22E+07        | 2.55E+07        | 2.5%        | 2.8% Price per kg: 1.2 US\$                                      |
| <b>Total</b>         |    |                 | <b>1.03E+09</b> | <b>100%</b> |                                                                  |

The total annual energy and material requirements as well as emissions of the refinery are summarized in Tab. 5.11. LPG use is approximated with the data set “natural gas, burned in industrial furnace”. The SO<sub>2</sub> emissions of the combustion of heavy fuel oil and coal are already included in the data set “heavy fuel oil, burned in industrial furnace 1MW, non-modulating” and “hard coal, burned in industrial furnace 1-10MW”, respectively. Particulates fractions are determined with standard data for non-ferrous metal industry<sup>9</sup>. Transport requirements are estimated to be 250 tkm lorry and 250 tkm train (average distance from the mines to the smelter, according to environmental report), for fossil fuels an average energy density of 40 MJ/kg is used. Where available, data from the PGM-plant is used to determine the requirement of gold- and silver treatment (Boliden, 2004). In this case, the energy requirements of the PGM-Plant are indicated in Tab. 5.11 as share of the whole refining process.

<sup>9</sup> PM2.5 82%, PM10 92% ([http://www.iiasa.ac.at/~rains/cgi-bin/rains\\_pm](http://www.iiasa.ac.at/~rains/cgi-bin/rains_pm), retrieved 6.4.2004).

### 5.1.3 Gold and silver production, Papua New Guinea (PG)

Data stem from the environmental report of Placer Dome Inc. (Placer Dome Inc., 2002b; Placer Dome Inc., 2003b) and Barrick (2006b) for the Misima Mine and the Porgera Mine. Both are open pit mines. The Misima Mine was in operation until 2004 and produced gold and silver. In January 2006, the Porgera Mine was sold to the Canadian company of Barrick. Actual data (2006) from Barrick is used where available, no environmental report has been published in the years 2004 and 2005. Since no actual production takes place in the Misima mine, the data of the last year of full activity (year 2000) is used as one production site of gold in Papua New Guinea (see Tab. 5.15 for production values).

The Porgera Mine is located in the Enga Province of the Papua New Guinea highlands about 550 kilometres north west of the capital Port Moresby and produces only gold.

The Misima mine is situated on an island 190 km east from the main island of Papua New Guinea. The distance to the capital Port Moresby is about 650 km. The tailings of Misima are disposed of with a pipeline in deep-sea (Placer Dome Inc., 2000).

Tab. 5.15 shows the production volume in 2000/2006, calculated turnover and shares in turnover of the different products of the Misima and the Porgera Mine.

The recovery rate (proportion of valuable material physically recovered in the processing of ore) is taken into account in order to define the resource extraction. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for Papua New Guinea is calculated with the quantity of ore milled and the corresponding production rate.

**Tab. 5.15: Production volume 2000 / 2006, calculated turnover and shares in turnover of the different products of the Misima and the Porgera Mine (Placer Dome Inc., 2001, Barrick, 2006a), Basis: prices 2004-2006 according to Tab. 2.5**

### Mining infrastructure

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (see Tab. 5.1: Gold and Silver production in Sweden). The lifetime of mines is assumed to be 50 years.

Land use is based on the figures from the environmental report (Tab. 5.16). Not all the area of the mine is in active use (disturbed area) at one time; the value in Tab. 5.16 is assumed to be the average share of the mine area in use. Therefore, the total area is occupied during an average of about 25 years according to the following formula:

$$\frac{\text{Disturbed area in active use}}{\text{Area disturbed during life of mine}} * \text{lifetime of mine} = \frac{1.17 * 10^7}{2.32 * 10^8} * 50y = 25y$$
 , the occupation of the mine is calculated as Disturbed area in active use \* 50y = Occupation, mineral extraction site

Tab. 5.16: Land use of the Misima and Porgera Mines in 2002 (Placer Dome Inc., 2002a)

| Land use                           |                | Misima 2000 | Porgera 2006 | Papua New Guinea | Remark                                                                       |

## Mining and refining

The recovery processes of the Misima Mine are cyanide leach and carbon in pulp (CIP), in the Porgera Mine pressure oxidation and cyanide leach. Both mines produce doré.

The following table (Tab. 5.18) sums up the total requirements and emissions of the Misima and Porgera Mines. For the Porgera Mine data from 2006 is used where available, the consumption of some material requirements is scaled with the weight of processed gold and data from the year 2002. For the Misima Mine data from 2000 is used, when the Misima Mine was still producing (Placer Dome Inc., 2001). Since the module “blasting” does not include the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive). The emissions to air and in water from the Misima and Porgera mines are as declared in the environmental reports, only liquid effluents have been modelled. Emissions to water head from the Misima-Mine to the ocean, whereas from Porgera they are into the river.

**Tab. 5.18: Material and energy requirements of the Misima Mine in 2000 (Placer Dome Inc., 2001) and the Porgera Mine in 2002 / 2006 (Placer Dome Inc., 2002b, Barrick, 2006b)**

<sup>1</sup> Electricity in Misima is produced from diesel and heavy fuel oil. Porgera's principal source of power is supplied by a 73-kilometre transmission line from the gas fired and PJV-owned Hides Power Station. The station has a total output of 62 megawatts ("MW"). A back up diesel power station is located at

the mine and has an output of 13MW. The average power requirement of the mine is about 60 MW. The environmental impacts of electricity use in Papua New Guinea are considered in the modules “diesel, burned in diesel-electric generating set” and “heavy fuel oil, burned in industrial furnace”.

- <sup>2</sup> An 18 MW diesel fired power station supplies electrical power. Diesel was used in the station due to the unavailability of previously supplied heavy fuel oil.
- <sup>3</sup> Process water is supplied from pit dewatering bores and in-pit water. Potable water is sourced from boreholes in the coastal limestone. The figure in the environmental report is 3.33E+12 l. However, as the discharge in 2002 is about 7.0E+9 l, the value in the report is assumed to be 1000 times too high and corrected to 3.33E+09 l.
- <sup>4</sup> The main water supply of the mine is the Waile Creek Dam, located approximately 7 kilometres from the mine. The reservoir has a capacity of approximately 717, 000 m<sup>3</sup> of water. Water for the grinding circuit is also extracted from Kogai Creek, which is located adjacent to the grinding circuit. The mine operates four water treatment plants for potable water and five sewage treatment plants.
- <sup>5</sup> The figure in the environmental report from 2000 was 0.24 kg. However, 2001-2003, the values are 23-47kg, so the figure for 2000 is assumed to be 100 times too small and is corrected to 24 kg.

The figures are allocated on the basis of the allocation factors shown in Tab. 5.15. Air emissions (zinc, copper and lead) are approximated with Swedish data. As Swedish data stem from a combined process, they were allocated to gold and silver for Sweden and scaled by the milled ore for Papua New Guinea. Transport distances are estimated to be 600 km for the materials on land (corresponds to the average distance from capital Port Moresby to the mines).

Since the mines produce doré gold (unrefined gold bullion bars containing between 60% and 95% gold), the refinery process is less complex than the refinery process of Rönnskär in Sweden. It is assumed, that the gold doré-bars undergo the treatment of Wohlwill electrolysis (for details see 5.2.2.1, “Gold / Silver, secondary, from electronic scrap in ecoinvent”). Due to the lack of specific data, the figure of refinement from electronic scrap is used: 1.63 kWh per kg gold (Renner et al., 2002a). The refinery of silver requires 0.6 kWh per kg of silver (Möbius electrolysis). No emissions were assumed, since on the one hand the high value of the processed material requires an efficient emission control and on the other hand, refinement is a hydrometallurgical process with low impact. The infrastructure is approximated with the facility of precious metal refinery. The unit process raw data are summarized in Tab. 5.19.

Tab. 5.19: Unit process raw data of gold and silver mining and refining in Papua New Guinea

| GeneralComment             | This data set includes land use of the considered mines incl. revegetated areas as well as estimates of buildings and machinery of the mine based on the data set non-ferrous metal, mine, surface/underground. | This multi-output process 'mining and refining, gold-silver deposit' delivers the two co-products 'gold, from combined gold-silver-production, at refinery' and 'silver, from combined gold-silver-production, at refinery'. This data set includes the mining in Papua New Guinea in open pit mines incl. land use. Air emissions are estimated. |

### 5.1.4 Gold and silver production, Chile (CL)

Data for the Mine “La Coipa” stem from the environmental report of Placer Dome Inc. (2002b). Since the mine has been sold in 2006 to Kinross Gold Corporation and Goldcorp Inc., no more recent data is available. Both enterprises do not publish their environmental data. Therefore, the older data from 2002 is used to model the gold- and silver production in Chile.

The La Coipa Mine produces gold and silver and is an open pit mine. Tab. 5.22 shows the production volume 2002 and calculated turnover of the La Coipa Mine. The recovery rate (proportion of valuable material physically recovered in the processing of ore) is taken into account in order to define the resource extraction. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for Chile is calculated with the quantity of ore milled and the corresponding production rate.

**Tab. 5.22: Production volume 2002, calculated turnover and shares in turnover of the different products of the La Coipa Mine (Placer Dome Inc., 2003a). Basis: prices 2005 according to Tab. 2.5.**

| Production        |       | La Coipa |                               |
|-------------------|-------|----------|-------------------------------|
| Ore milled        | kg    | 3.17E+09 |                               |
| Production Gold   | kg    | 2.99E+03 |                               |
| Production Silver | kg    | 1.12E+05 |                               |
| Value Gold        | US\$  | 4.69E+07 | Value of 1kg Gold: 15680 US\$ |
| Value Silver      | US\$  | 3.01E+07 | Value of 1kg Silver: 269 US\$ |
| Allocation Gold   |       | 60.9%    |                               |
| Allocation Silver |       | 39.1%    |                               |
| Head grade        |       |          |                               |
| Gold              | kg/kg | 1.11E-06 |                               |
| Silver            | kg/kg | 4.16E-05 |                               |
| Recovery rate     |       | 85%      |                               |

### Mining infrastructure

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (see Tab. 5.1: Gold and Silver production in Sweden). The lifetime of mines is assumed to be 50 years.

Land use is based on the figures from the environmental report (Tab. 5.23). Not all the area of the mine is in active use at one time; the value in Tab. 5.23 is assumed to be the average share of the mine area in use. Therefore, the total area is occupied during an average of about 43 years, according to formula:

$$\frac{\text{Disturbed area in active use}}{\text{Area disturbed during life of mine}} * \text{lifetime of mine} = \frac{1.16 * 10^7}{1.34 * 10^8} * 50y = 43y$$
 , the occupation of the mine is calculated as Disturbed area in active use \* 50y = Occupation, mineral extraction site

**Tab. 5.23: Land use of the La Coipa Mine in 2002 (Placer Dome Inc., 2004).**

| Land use                                   |                | La Coipa | Remark                                                                       |
|--------------------------------------------|----------------|----------|------------------------------------------------------------------------------|
| Area disturbed during life of mine         | m <sup>2</sup> | 1.34E+07 | Transformation, from unknown and Transformation, to mineral extraction site, |
| Disturbed area in active use <sup>1)</sup> | m <sup>2</sup> | 1.16E+07 | Occupation, mineral extraction site, during 50 years                         |
| Area available for revegetation            | m <sup>3</sup> | 1.72E+06 | Transformation to unknown                                                    |
| Area revegetated                           | m <sup>2</sup> | 3.00E+04 | added in "Transformation, to heterogeneous, agricultural"                    |

<sup>1</sup> This figure is 0 in the original data, which is assumed to be a mistake. The area in active use is therefore calculated as the area disturbed during life of mine minus area available for revegetation and area revegetated.

Tab. 5.24: Unit process raw data for the gold and silver mine in Chile.

|                | Name                                             | Location | Infrastructure | Process | Unit | mine, gold and silver | Uncertainty Type | Standard Deviation 95% | General Comment                                            |

### Mining and refining

The processing plant consists of primary crushing, a pre-crushing circuit, (semi autogenous ball mill crushing) grinding, leaching, filtering and washing, Merrill-Crowe plant and doré refinery. The Merrill-Crowe metal recovery circuit is better than a carbon-in-pulp system for the high-grade silver material. Tailings are filtered to recover excess water as well as residual cyanide and metals. A dry tailings disposal system was preferred to a conventional wet tailings impoundment because of site-specific environmental considerations. The following table (Table 5.25) sums up the total energy and material requirements of the La Coipa Mine in 2002.

Table 5.25: Energy and material requirements of the La Coipa Mine in 2002 (Placer Dome Inc., 2002b).

| Energy                           |                | La Coipa | Remark                                                                                            |
|----------------------------------|----------------|----------|---------------------------------------------------------------------------------------------------|
| Electricity for mining           | kWh            | 1.60E+08 | Chilean mix 1) approximated with the UCTE mix                                                     |
| Electricity for refining         | kWh            | 7.21E+04 | assumed with Möbius / Wohlwill-electrolysis, Chilean mix 1) approximated with the UCTE mix        |
| Diesel (generators)              | MJ             | 4.18E+08 | Diesel, burned in diesel-electric generating set                                                  |
| Diesel (mobile equipment)        | l              | 9.44E+07 | Diesel, burned in building machine                                                                |

| Cadmium, ion                     | kg             | 5.80E+02 | estimated with Data from PG, scaled by milled ore                                                 |
| Copper, ion                      | kg             | 3.21E+04 | estimated with Data from PG, scaled by milled ore                                                 |
| Cyanide                          | kg             | 5.22E+04 | estimated with Data from PG, scaled by milled ore                                                 |
| Lead                             | kg             | 8.49E+01 | estimated with Data from PG, scaled by milled ore                                                 |
| Mercury                          | kg             | 1.32E+00 | estimated with Data from PG, scaled by milled ore                                                 |
| Nickel, ion                      | kg             | 7.70E+03 | estimated with Data from PG, scaled by milled ore                                                 |
| Zinc, ion                        | kg             | 2.05E+05 | estimated with Data from PG, scaled by milled ore                                                 |
| <b>Emissions to Air</b>          |                |          |                                                                                                   |
| Carbon Dioxide (from explosives) | kg             | 2.75E+05 | Calculation, based on data from Newmont (2005)                                                    |
| Zinc                             | kg             | 6.99E-01 | estimated with Data from SE, scaled by milled ore                                                 |
| Copper                           | kg             | 2.53E+00 | estimated with Data from SE, scaled by milled ore                                                 |
| Lead                             | kg             | 8.24E-01 | estimated with Data from SE, scaled by milled ore                                                 |
| <b>Disposal</b>                  | kg             | 2.25E+09 | estimated with data from PG, in LCI as: Disposal, sulphidic tailings                              |

<sup>1</sup> Chilean electricity mix in 2005 (Nationmaster, 2004): fossil fuel 47%, hydro 51.5%, other 1.5%.

There are existing facilities for water extraction in the Salar de Maricunga, which is located 50 kilometres southeast of La Coipa. There is a water pump system that collects the water from five wells. The water is accounted for as ground water (water, well, in ground).

Water emissions are approximated with figures of the mines in Papua New Guinea, material use (with exception of cyanide) with figures of Australian data for gold and silver production (Stewart, 1999), see also chapter 5.1.9), air emissions (zinc, copper and lead) with Swedish data. As Swedish data stand for a combined process, they are allocated to gold and silver for Sweden and used in this form for Chile. Cyanide is accounted for as sodium cyanide, which is commonly used in the gold mining. Since the module "blasting" does not include the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive). Water emissions are assumed to be emitted to rivers. Transports of materials are estimated to be 600 km by truck. Data on the amount of tailings disposal is approximated with data of mines in Papua New Guinea.

Since the mines produce doré gold (unrefined gold bullion bars containing between 60% and 95% gold), the refinery process is less complex than the refinery process of Rönnskär in Sweden. It is assumed, that the gold doré-bars undergo the treatment of Wohlwill electrolysis (for details see 5.2.2.1, "Gold / Silver, secondary, from electronic scrap inecoinvent"). Due to the lack of specific data about primary refinement, the figure of refinement from electronic scrap is used: 1.63 kWh per kg gold

(Renner et al., 2002a). The refinery of silver requires 0.6 kWh per kg of silver (Möbius electrolysis). No emissions were assumed, since on the one hand the high value of the processed material requires an efficient emission control and on the other hand, refinement is a hydrometallurgical process with low impact. The infrastructure is approximated with the facility of precious metal refinery. The unit process raw data are summarized in Tab. 5.26.

**Tab. 5.26: Unit process raw data of gold and silver mining and refining in Chile**

| GeneralComment             | This data set includes land use of the considered mines incl. revegetated areas as well as estimates of buildings and machinery of the mine based on the data set non-ferrous metal, mine, surface/underground. | This multi-output process 'mining and refining, gold-silver deposit' delivers the two co-products 'gold, from combined gold-silver-production, at refinery' and 'silver, from combined gold-silver-production, at refinery'. This data set includes the mining in Chile in open pit mine incl. land use. Air emissions are estimated. |

### 5.1.5 Gold and silver production, Peru (PE)

Yanacocha is a gold mine in northern Peru, considered one of the biggest and most profitable in the world. The Yanacocha-Mine is located in the Cajamarca Province of the Peruvian highlands about 450 kilometres north of the capital Lima and produces gold and silver. Data for the Mine "Yanacocha" stem from the environmental reports of Newmont (2005a) and Arana (2002). Newmont is the major shareholder together with Buenaventura, a Peruvian company. In 2005, Yanacocha produced 103'000

kg of gold. Minera Yanacocha consists of five open pit mines, four leach pads, two gold recovery plants, and a crushing and agglomeration facility.

The recovery rate (proportion of valuable material physically recovered in the processing of ore) is taken into account in order to define the resource extraction. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for Peru is calculated with the quantity of ore milled, the corresponding production rate and the recovery rate.

**Tab. 5.29 Production, Allocation and Recovery rate of the various metals produced in 2005 by the Yanacocha-Mines (Newmont, 2005a; Arana, 2002), the prices are from Tab. 2.5.**

### Mining infrastructure

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (see Tab. 5.1: Gold and Silver production in Sweden). The lifetime of mines is assumed to be 50 years.

Land use is based on the figures from the environmental report (Tab. 5.30). Not all the area of the mine is in active use at one time; the value in Tab. 5.30 is assumed to be the average share of the mine area in use. Therefore, the total area is occupied during an average of about 42 years, according to the following formula:

$$\frac{\text{Disturbed area in active use}}{\text{Area disturbed during life of mine}} * \text{lifetime of mine} = \frac{2.68 * 10^7}{3.19 * 10^8} * 50y = 42y$$
 , the occupation of the mine is calculated as  $\text{Disturbed area in active use} * 50y = \text{Occupation, mineral extraction site}$

**Tab. 5.30: Land use of the Yanacocha-Mine in 2005 (Newmont, 2005a)**

## Mining and refining

The ore mined at Minera Yanacocha is broken up into small pieces and placed in layers, forming a hill of ore known as a leach pad. A diluted sodium-cyanide solution is dripped onto the leach pad to extract the gold. The gold-laden solution is collected at the bottom of the pad for processing.

Table 5.25 displays the total energy and material requirements of the Yanagocha-Mines in 2005.

Tab. 5.32: Energy and material requirements of the Yanacocha-Mines in 2005 (Newmont, 2005a)

- 1 Peruvian electricity mix in 2005 (Nationmaster, 2004): fossil fuel 14.5%, hydro 84.7% others: 0.8%, Brazilian electricity mix: fossil fuel 9.9%, hydro: 83.7, others: 6.4%

Since no reliable measures or values are available, water emissions are approximated with the figures of the mines in Papua New Guinea. The use of charcoal and zinc is estimated with figures of Australian data for gold and silver production (Stewart, 1999, see also chapter 5.1.9). Airborne emissions as carbon monoxide, nitrogen oxide, particulates and sulfur dioxide due to burning of fossil fuels are already inventoried and therefore not accounted in this LCI. The disposal of charcoal has been neglected. Since the module “blasting” does not include the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive). Cyanide is accounted for as sodium cyanide, which is commonly used in the gold mining. Water emissions are assumed to be emitted to rivers. Transports of materials are estimated to be 600 km per truck. Data

about amounts of tailings disposal is approximated with data of gold/silver mines in Papua New Guinea.

Since the mines produce doré gold (unrefined gold bullion bars containing between 60% and 95% gold), the refinery process is less complex than the refinery process of Rönnskär in Sweden. It is assumed, that the gold doré-bars undergo the treatment of Wohlwill electrolysis (for details see 5.2.2.1, “Gold / Silver, secondary, from electronic scrap in ecoinvent”). Due to the lack of specific data, the figure of refinement from electronic scrap is used: 1.63 kWh per kg gold (Renner et al., 2002a). The refinery of silver requires 0.6 kWh per kg of silver (Möbius electrolysis). No emissions were assumed, since on the one hand the high value of the processed material requires an efficient emission control and on the other hand, refinement is a hydrometallurgical process with low impact. The infrastructure is approximated with the facility of precious metal refinery. The unit process raw data are summarized in Tab. 5.33 .

Tab. 5.33: Unit process raw data of gold and silver mining and refining in Peru

| GeneralComment             | This data set includes land use of the considered mines incl. revegetated areas as well as estimates of buildings and machinery of the mine based on the data set non-ferrous metal, mine, surface/underground. |  | This multi-output process 'mining and refining, gold-silver deposit' delivers the two co-products 'gold, from combined gold-silver-production, at refinery' and 'silver, from combined gold-silver-production, at refinery'. This data set includes the mining in Peru in open pit mines incl. land use. Air emissions are estimated. |  |

## 5.1.6 Gold production, Canada (CA)

Data stem from the environmental report of Placer Dome Inc. (2002b) for the Campbell, Musselwhite and Porcupine Mines. Since the mines have been sold in 2006 to Kinross Gold Corporation and Goldcorp Inc., no actual data is available. Both enterprises do not publish their environmental data. Therefore, data from 2002 is used to model the gold production in Canada.

The mines produce only gold. Campbell and Musselwhite are underground, Porcupine has underground and open pit mines. Tab. 5.36 shows the production volume in year 2002 of the Campbell, Musselwhite and Porcupine Mines. The recovery rate (proportion of valuable material physically recovered in the processing of ore) is taken into account in order to define the resource extraction. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for Canada is calculated with the quantity of ore milled, the corresponding production rate and the recovery rate.

**Tab. 5.36: Production volume in 2002 of the Campbell, Musselwhite and Porcupine Mines (Placer Dome Inc., 2003a).**

| Production      |       | Campbell | Musselwhite | Porcupine | Canada          |
|-----------------|-------|----------|-------------|-----------|-----------------|
| Ore milled      | kg    | 3.57E+08 | 7.87E+08    | 1.10E+09  | <b>2.24E+09</b> |
| Production Gold | kg    | 6.01E+03 | 4.43E+03    | 3.17E+03  | <b>1.36E+04</b> |
| Head grade      |       |          |             |           |                 |
| Gold            | kg/kg | 1.98E-05 | 6.62E-06    | 3.39E-06  | <b>7.14E-06</b> |
| Recovery rate   |       |          |             |           | <b>85%</b>      |

### Mining infrastructure

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (see Tab. 5.1: Gold and Silver production in Sweden). The lifetime of mines is assumed to be 50 years.

**Tab. 5.37: Land use of the Campbell, Musselwhite and Porcupine Mines in 2002 (Placer Dome Inc., 2002b).**

| Land use                           |                | Campbell | Musselwhite | Porcupine | Canada          | Remark                                                                       |
|------------------------------------|----------------|----------|-------------|-----------|-----------------|------------------------------------------------------------------------------|
| Area disturbed during life of mine | m <sup>2</sup> | 1.60E+06 | 4.44E+06    | 1.08E+08  | <b>1.14E+08</b> | Transformation, from unknown and Transformation, to mineral extraction site, |
| Disturbed area in active use       | m <sup>2</sup> | 6.80E+05 | 2.91E+06    | 4.70E+07  | <b>5.06E+07</b> | Occupation, mineral extraction site, during 50 years                         |
| Area available for revegetation    | m <sup>3</sup> | 1.50E+05 | 1.31E+06    | 4.80E+07  | <b>4.95E+07</b> | Transformation to unknown                                                    |
| Area revegetated                   | m <sup>2</sup> | 4.70E+05 | 8.00E+04    | 1.08E+07  | <b>1.14E+07</b> | added in "Transformation, to heterogeneous, agricultural"                    |
| Area that meets final objectives   | m <sup>3</sup> | 3.00E+05 | 0.00E+00    | 2.20E+06  | <b>2.50E+06</b> | added in "Transformation, to heterogeneous, agricultural"                    |

Land use is based on the figures from the environmental report (Tab. 5.37). Not all the area of the mine is in active use at one time; the value in Tab. 5.37 is assumed to be the average share of the mine area in use. Therefore, the total area is occupied during an average of about 22 years, according to the formula

$$\frac{\text{Disturbed area in active use}}{\text{Area disturbed during life of mine}} * \text{lifetime of mine} = \frac{5.06 * 10^7}{1.14 * 10^8} * 50y = 22y$$
 , the occupation of the mine is calculated as Disturbed area in active use \* 50y = Occupation, mineral extraction site

Tab. 5.38: Unit process raw data for the gold and silver mine in Canada.

### Mining and refining

In the Porcupine Mines, gold is recovered using a combination of gravity concentration, milling and cyanidation techniques. The milling process consists of primary crushing, secondary crushing, rod/ball mill grinding, gravity concentration, cyanide leaching, carbon-in-pulp gold recovery, stripping, electrowinning and refining.

In the Campbell Mine, the ore from the mine, after crushing and grinding, is processed by gravity separation, flotation, pressure oxidation, cyanidation and carbon-in-pulp process followed by electrowinning and gold refining to doré on site.

The Musselwhite Mine uses gravity separation, carbon in pulp, electrowinning and gold refining to doré on site. The following table (Tab. 5.39) shows the total requirements and emissions of the Campbell, Musselwhite and Porcupine Mines in 2002 as well as the total for Canada.

**Tab. 5.39: Annual requirements and emissions of the Campbell, Musselwhite and Porcupine Mines in 2002 (Placer Dome Inc., 2002b).**

<sup>1</sup> Electricity mix Canada in 2000 (GENI (2004)): fossil 26%, hydro 61%, nuclear 12%, other 2%. Campbell mine uses only hydro power.

<sup>2</sup> The consumption of the different energy sources in Musselwhite and Porcupine is calculated on the basis of their share in the figures of the Campbell mine.

Material use is approximated with figures from Australian data for gold and silver production (Stewart, 1999), whereas air emissions (zinc, copper and lead) are modelled with Swedish data. As Swedish data stem for a combined process, they are allocated to gold and silver for Sweden and used

in this form for Canada. Electricity supply mix of Canada is approximated with the NORDEL electricity mix (Nordic countries power association) that has a related share of hydroelectric power production (The higher part of fossil electricity generation in NORDEL is somewhat compensated by the use of exclusively hydro by the Campbell-Mine). Explosive use is estimated with Data from US. Since the module “blasting” not includes the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive). Water emissions are assumed to be emitted to rivers. Estimation of transport is based on standard distances. Data about amounts of tailings disposal is approximated with data of mines in Papua New Guinea.

Since the mines produce doré gold (unrefined gold bullion bars containing between 60% and 95% gold), the refinery process is less complex than the refinery process of Rönnskär in Sweden. It is assumed, that the gold doré-bars undergo the treatment of Wohlwill electrolysis (for details see 5.2.2.1, “Gold / Silver, secondary, from electronic scrap in ecoinvent”). Due to the lack of specific data, the figure of refinement from electronic scrap is used: 1.63 kWh per kg gold (Renner et al., 2002a). No emissions were assumed, since on the one hand the high value of the processed material requires an efficient emission control and on the other hand, refinement is a hydrometallurgical process with low impact. The infrastructure is approximated with the facility of precious metal refinery. The unit process raw data are summarized in Tab. 5.40.

## 5. System Characterisation

Tab. 5.40: Unit process raw data of gold mining and refining in Canada.

### 5.1.7 Gold production, United States of America (US)

Data stem from the environmental report of Barrick (2006b) for the Bald Mountain, Cortez, Golden Sunlight, Goldstrike and Round Mountain Mines. Since the mines have been sold in 2006 from the company of Placer Dome to Barrick, previous environmental reports of Placer Dome Inc. (2002b) are used as well.

The data about the mines of Nevada and Golden Giant are from Newmont (2005b). The mines are either underground or open pits. All mines produce only gold. Tab. 5.42 shows the production volume 2005 of the considered US Mines. The recovery rate (proportion of valuable material physically recovered in the processing of ore) is taken into account in order to define the resource extraction. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for United States is calculated with the quantity of ore milled, the corresponding production rate and the recovery rate.

### Mining infrastructure

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (see Tab. 5.1: Gold and Silver production in Sweden). The lifetime of mines is assumed to be 50 years.

Land use is based on the figures from the environmental report of Newmont (2005b) and the previous environmental report of Placer Dome Inc. (2002b). Not all the area of the mine is in active use at one time; the value in Tab. 5.56 is assumed to be the average share of the mine area in use. Therefore, the total area is occupied during an average of about 43 years, according to the formula:

$$\frac{\text{Disturbed area in active use}}{\text{Area disturbed during life of mine}} * \text{lifetime of mine} = \frac{7.04 * 10^8}{8.14 * 10^8} * 50y = 43y$$
, the occupation of the mine is calculated as  $\text{Disturbed area in active use} * 50y = \text{Occupation, mineral extraction site}$

## Mining and refining

In the Bald Mountain Mines, the ore treatment method is based on conventional heap leaching technology followed by carbon absorption. The loaded carbon is stripped and refined in the newly commissioned refinery on site. Water is supplied by wells located on the mine property. Grid power was brought to Bald Mountain Mine in 1996. For this purpose, one 27-kilometre 69 KVA power line was constructed from the Alligator Ridge Mine substation to the grid.

At the Golden Sunlight Mines, the ore treatment plant is based on conventional carbon-in-pulp technology, with the addition of a Sand Tailings Retreatment (STR) gold recovery plant to recover gold that would otherwise be lost to tailings. The STR circuit removes the heavier gold bearing pyrite from the sand portion of the tailings by gravity separation. The gold is refined into doré at the mine. Tailing from the mill is discharged to an impoundment area where the solids are allowed to settle so the water can be reused. A cyanide recovery/destruction process was commissioned in 1998. It eliminates the hazard posed to wildlife at the tailings impoundment by lowering cyanide concentrations below 20 mg/l. Fresh water for ore processing, dust suppression, and fire control is supplied from the Jefferson Slough, which is an old natural channel of the Jefferson River. Ore processing also uses water pumped from the tailings impoundment. Pit water is treated in a facility located in the mill complex prior to disposal or for use in dust control. Drinking water is made available by filtering fresh water through an on-site treatment plant. Electric power is provided from a substation at the south property boundary. North-Western Energy supplies electricity the substation. Small diesel generators are used for emergency lighting. A natural gas pipeline supplies gas for heating buildings, a crusher, air scrubber, boiler, carbon reactivation kiln, and refining furnaces.

At the Cortez Mine, three different metallurgical processes are employed for the recovery of gold. The process used for a particular ore is determined based on grade and metallurgical character of that ore. Lower grade oxide ore is heap leached, while higher-grade non-refractory ore is treated in a conventional mill using cyanidation and a carbon-in-leach ("CIL") process. When carbonaceous ore is processed by Barrick, it is first dry ground, and then oxidized in a circulating fluid bed roaster, followed by CIL recovery. In 2002 a new leach pad and process plant was commissioned. This facility will be capable of processing 164 million tonnes of heap leach ore over the life of the asset. Heap leach ore production is hauled directly to heap leach pads for gold recovery. Water for process use is supplied from the open pit dewatering system. Approximately 90 litres per second of the pit dewatering volume is diverted for plant use. Electric power is supplied by Sierra Pacific Power Company ("SPPC") through a 73 kilometre, 120 kV transmission line. A long-term agreement is in place with SPPC to provide

power through the regulated power system. The average power requirement of the mine is about 160 GWh/year.

Further information about the mines and their infrastructure can be found in the corresponding chapters of Barrick (2006b); Newmont (2005b) and Barrick (2006b). The following table (Tab. 5.45) shows the requirements and emissions of the considered mines as well as the US total.

Material use of zinc and carbon is approximated with figures from Australian data for gold and silver production (Stewart, 1999). The consumption of Lime and caustic (Sulphuric Acid / Hydrochloric Acid) was taken from the environmental reports (where available), other ways estimated with the Australian values (Stewart, 1999).

The water emissions are estimated with data of Australia, it is assumed that they are emitted to rivers. Since the module “blasting” does not include the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive). The transport of materials is calculated with ecoinvent standard distances for Europe. Data of tailing disposal are approximated with data from Papua New Guinea.

Since the mines produce doré gold (unrefined gold bullion bars containing between 60% and 95% gold), the refinery process is less complex than the refinery process of Rönnskär in Sweden. It is assumed, that the gold doré-bars undergo the treatment of Wohlwill electrolysis (for details see 5.2.2.1, “Gold / Silver, secondary, from electronic scrap in ecoinvent”). Due to the lack of specific data, the figure of refinement from electronic scrap is used: 1.63 kWh per kg gold (Renner et al., 2002a). No emissions were assumed, since on the one hand the high value of the processed material requires an efficient emission control and on the other hand, refinement is a hydrometallurgical process with low impact. The infrastructure is approximated with the facility of precious metal refinery. The unit process raw data are summarized in Tab. 5.47.

### 5.1.8 Gold production, South Africa (ZA)

Data stem from the environmental report of Western Areas Limited (2006) for the South Deep Mine. The mine produces only gold and is an underground mine. Tab. 5.49 shows the production volume 2005 of the South Deep Mine. The recovery rate (proportion of valuable material physically recovered in the processing of ore) is taken into account in order to define the resource extraction. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for South Africa is calculated with the quantity of ore milled, the corresponding production rate and the recovery rate.

Tab. 5.49: Production volume of the South Deep Mine in 2005 (Western Areas Limited, 2006).

| South Deep      |           |          |
|-----------------|-----------|----------|
| Production Gold | kg        | 1.43E+04 |
| Ore milled      | kg        | 2.14E+09 |
| Head grade      |           |          |
| Gold            | kg/kg ore | 6.92E-06 |
| Recovery rate   |           | 97%      |

### Mining infrastructure

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (see Tab. 5.1: Gold and Silver production in Sweden). The lifetime of mines is assumed to be 50 years.

Land use is based on the figures from the previous environmental report of Placer Dome Inc. (2002b) see Tab. 5.50).

Tab. 5.50: Land use of the South Deep Mine in 2002 (Placer Dome Inc., 2002b)

### Mining and refining

The ore is mined by conventional underground long wall mining methods (50%) and mechanized drift and fill trackless methods (50%). The conventional stope ore is drilled, blasted and scraped or washed into a series of gullies that feed an ore pass system. The trackless ore is drilled, blasted and loaded with scoop trams to internal ore passes. The ore is then transported by rail to a shaft loading system and hoisted to surface. During June 2002 the new gold extraction plant was commissioned. It includes a two stage milling circuit (SAG Mill and Ball Mill), a gravity gold recovery circuit inclusive of leach reactors and a pump cell CIP plant. It has a planned capacity of 7,200 tonnes per day. It will be capable of producing at low cost and high extraction efficiency after an increased steady state mill feed is obtained. ESKOM is the supplier of electrical energy in the country; electricity at 132 kilovolts (kV) voltage level is supplied to South Deep from the national grid. The annual power requirement of the mine is approximately 610 GWh. The underground feed is presently 6.6kV with a plan for 11kV feed down the new South Deep Main Shaft complex.

Since the module “blasting” does not include the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive). Air emissions are approximated with Australian data, based on produced gold. Water emissions are estimated on the previous environmental report of Placer Dome Inc. (2002b) and assumed to be emitted to rivers. Transport of materials is calculated on the basis of standard distances. Data about amounts of tailing disposal is approximated with data from Papua New Guinea.

The following table (Tab. 5.52) sums up the total requirements and emissions of the South Deep Mine in 2005.

## 5. System Characterisation

Tab. 5.52: Requirements and emissions of the South Deep Mine in 2002 (Placer Dome Inc., 2002b).

<sup>1</sup> South African electricity mix in 2007 (Nationmaster, 2004): fossil fuel 93.5 %, hydro 1.1%, nuclear 5.5%.

Since the mines produce doré gold (unrefined gold bullion bars containing between 60% and 95% gold), the refinery process is less complex than the refinery process of Rönnskär in Sweden. It is assumed, that the gold doré-bars undergo the treatment of Wohlwill electrolysis (for details see 5.2.2.1, “Gold / Silver, secondary, from electronic scrap inecoinvent”). Due to the lack of specific data, the figure of refinement from electronic scrap is used: 1.63 kWh per kg gold (Renner et al., 2002a). No emissions were assumed, since on the one hand the high value of the processed material requires an efficient emission control and on the other hand, refinement is a hydrometallurgical process with low

impact. The infrastructure is approximated with the facility of precious metal refinery. The unit process raw data are summarized in Tab. 5.53.

Tab. 5.53: Unit process raw data of gold mining and refining in South Africa

### 5.1.9 Gold production, Australia (AU)

Data stem from the environmental report of Newmont (2005b) for the Kalgoorlie, Jundee, Tanami and Pajingo Mines. The mines produce only gold. Tanami and Pajingo are underground mines, Kalgoorlie open pit, and Jundee open pit and underground. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for Australia is calculated with the quantity of ore milled, the corresponding production rate and the recovery rate.

Tab 5.55 shows the production volume in 2005 of the considered Australian mines. The recovery rate (proportion of valuable material physically recovered in the processing of ore) is taken into account in order to define the resource extraction. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for Australia is calculated with the quantity of ore milled, the corresponding production rate and the recovery rate.

**Tab 5.55: Production volume 2005 of the Kalgoorlie, Jundee, Tanami and Pajingo Mines (Newmont, 2005b).**

### Mining infrastructure

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (see Tab. 5.1: Gold and Silver production in Sweden). The lifetime of mines is assumed to be 50 years.

Land use is based on the figures from the environmental report (Tab. 5.56). Not all the area of the mine is in active use at one time; the value in Tab. 5.56 is assumed to be the average share of the mine area in use. Therefore, the total area is occupied during an average of about 28 years, according to the formula:

$$\frac{\text{Disturbed area in active use}}{\text{Area disturbed during life of mine}} * \text{lifetime of mine} = \frac{3.33 * 10^7}{6.00 * 10^8} * 50y = 28y, \text{ the occupation of the mine is calculated as } \text{Disturbed area in active use} * 50y = \text{Occupation, mineral extraction site}$$

**Tab. 5.56: Land use of the Kalgoorlie, Jundee, Tanami and Pajingo Mines (Newmont, 2005b)**

| Land use                           |                | Kalgoorlie | Jundee   | Tanami   | Pajingo  | Australia | Remark                                                                       |

## Mining and refining

Although the production of gold and silver was assessed in an older detailed study (Stewart, 1999), the production of silver is neglected due to the low production (see Tab. 5.58) and the absence of actual data. Nevertheless, the data from the mentioned study has been used as a proxy value for material requirements, where actual data is lacking. The allocation for gold and silver (see Tab. 5.58) is done by economical values with prices of Tab. 2.5.

Tab. 5.58: Production of gold / silver and material requirement in gold / silver mining in the year 1999 (Stewart, 1999)

| Production        | Australia | Allocation | per kg gold | per kg silver |
|-------------------|-----------|------------|-------------|---------------|
| Gold              | 3.00E+05  | 99.81%     |             |               |
| Silver            | 3.40E+04  | 0.19%      |             |               |
| Material Use      |           |            |             |               |
| Lime              | 1.90E+7   |            | 6.32E+01    | 1.04E+00      |
| Sodium hydroxide  | 3.50E+6   |            | 1.16E+01    | 1.92E-01      |
| Hydrochloric acid | 4.10E+6   |            | 1.36E+01    | 2.25E-01      |
| Zinc              | 8.70E+5   |            | 2.89E+00    | 4.77E-02      |
| Carbon            | 5.10E+6   |            | 1.70E+01    | 2.79E-01      |
| Sulphuric acid    | 2.00E+5   |            | 6.65E-01    | 1.10E-02      |

The following table (Tab. 5.59) sums up the total requirements and emissions of the Kalgoorlie, Jun-dee, Tanami and Pajingo Mines in 2005. Information stems from the environmental reports. Carbon and zinc consumption is calculated with data from Stewart (1999).

Tab. 5.59: Energy and material requirements of the Kalgoorlie, Jundee, Tanami and Pajingo Mines (Newmont, 2005b)

| Australia                 |                |            |          |          |          |           |                                                                                                                                   |

<sup>1)</sup> Australian electricity mix (Nationmaster, 2004): fossil fuel 90.8%, hydro 8.3%, other 0.9%)

Water emissions are taken from data of the Granny Smith Mine (Placer Dome Inc., 2003a) for arsenic, and from data of the Henty Mine (Placer Dome Inc., 2003a) for the other water emissions. They are assumed to be released into rivers. Data about amounts of tailings disposal is approximated with data from Papua New Guinea. Since the module "blasting" does not include the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive).

Since the mines produce doré gold (unrefined gold bullion bars containing between 60% and 95% gold), the refinery process is less complex than the refinery process of Rönnskär in Sweden. It is assumed, that the gold doré-bars undergo the treatment of Wohlwill electrolysis (for details see 5.2.2.1, "Gold / Silver, secondary, from electronic scrap inecoinvent"). Due to the lack of specific data, the figure of refinement from electronic scrap is used: 1.63 kWh per kg gold (Renner et al., 2002a). No emissions were assumed, since on the one hand the high value of the processed material requires an efficient emission control and on the other hand, refinement is a hydrometallurgical process with low impact. The infrastructure is approximated with the facility of precious metal refinery.

Tab. 5.60 Emissions of the Kalgoorlie, Jundee, Tanami and Pajingo Mines (Newmont, 2005b)

| Emissions to Water               |    | Kalgoorlie | Jundee   | Tanami   | Pajingo  | Australia | Remark                                                                                                             |

### 5.1.10 Gold production, Tanzania (TZ)

Data stem from the environmental report of Placer Dome Inc. (2005) and Barrick (2006b) for the North Mara Mine. The mine produces only gold and is an open pit mine. Tab 5.63 shows the production volume in 2005 of the North Mara Mine. The recovery rate (proportion of valuable material physically recovered in the processing of ore) is taken into account in order to define the resource extraction. The average concentration (head grade, expressed in kg metal per kg ore) of metals in ore for Tanzania is calculated with the quantity of ore milled, the corresponding production rate and the recovery rate.

Tab 5.63: Production volume in 2004 of the North Mara Mine (Placer Dome Inc., 2005).

| Production      |           | North Mara |                                             |

### Mining infrastructure

This data set includes land use as well as rough estimates on buildings and machines necessary in gold mining. It is assumed, that the quantities of machinery as well as surface and volume of buildings are equal to the generic mine. This approach is rough, and the uncertainty is rather high. As the mined ore from the generic mine is some orders of magnitude lower than the mine in focus, a proportional scaling by milled ore will lead to a higher mistake (see Tab. 5.1: Gold and Silver production in Sweden). The lifetime of mines is assumed to be 50 years.

Tab, 5.64: Land use of North Mara Mine in 2004 (Placer Dome Inc., 2005).

| Land use                           |                | North Mara | Remark                                                                       |
|------------------------------------|----------------|------------|------------------------------------------------------------------------------|
| Area disturbed during life of mine | m <sup>2</sup> | 3.72E+06   | Transformation, from unknown and Transformation, to mineral extraction site, |
| Disturbed area in active use       | m <sup>2</sup> | 2.92E+06   | Occupation, mineral extraction site, during 50 years                         |
| Area revegetated                   | m <sup>2</sup> | 3.00E+04   | added in "Transformation, to heterogeneous, agricultural"                    |

Land use is based on the figures from the environmental report (Tab. 5.56). Not all the area of the mine is in active use at one time; the value in Tab. 5.56 is assumed to be the average share of the mine area in use. Therefore, the total area is occupied during an average of about 39 years, according to the formula:

$$\frac{\text{Disturbed area in active use}}{\text{Area disturbed during life of mine}} * \text{lifetime of mine} = \frac{2.92 * 10^6}{3.72 * 10^6} * 50y = 39y$$

, the occupation of the mine is calculated as Disturbed area in active use \* 50y = Occupation, mineral extraction site

Tab. 5.65: Unit process raw data of the gold mine in Tanzania.

|                | Name                                             | Location | Infrastructure | Process | Unit    | mine, gold      | Uncertainty Type | Standard Deviation 95%                                | General Comment |

### Mining and refining

Ore is fed via a single jaw crusher into a secondary crusher and then onto a crushed ore stockpile. The crushed ore is reclaimed from the stockpile and conveyed into an open circuit mill before passing to a closed circuit ball mill regrind. A gravity separation circuit is used to scalp free gold from regrind circuit. The ore is then processed via cyanidation and carbon in leach, followed by electrowinning and gold refining to doré on site.

Water for processing is pumped from the Mara River, which is located three kilometres from the processing plant site. The water is pumped into a raw water dam which can store up to three months water demand. A plant at the mine treats water for own use. Placer Dome Tanzania has a license to extract 4,200 cubic metres of water daily from the river. The following table (Tab. 5.66) sums up the total requirements and emissions of the North Mara Mine in 2005.

Material use (except for cyanide and explosives) is approximated with figures from Australian data for gold mining (Stewart, 1999), air emissions with Australian Data. Since the module “blasting” does not include the CO<sub>2</sub> emissions from explosives, they are calculated with the factor of the mines of Newmont (2005b) (0.16 kg CO<sub>2</sub> per kg explosive). Water emissions are assumed to be emitted to rivers and are estimated on the base of data for South Africa. Estimation of transport is based on standard distances for Europe. Data about amounts of tailings disposal are approximated with data of mines in Papua New Guinea.

Tab. 5.66: Requirements and emissions of the North Mara Mine in 2005 (Placer Dome Inc., 2005).

| Energy                           |                | North Mara | Remark                                                                                                             |

- 1 Neither a Tanzanian electricity mix nor the exact place of refinement are available, therefore we assumed the use of CENTREL-electricity mix for its high share of fossil electricity generation.
- 2 Estimation, based on emissions in South Africa, scaled by processed gold (Placer-Dome, 2002).
- 3 Estimation, based on emissions in Australia, scaled by processed gold.

Since the mines produce doré gold (unrefined gold bullion bars containing between 60% and 95% gold), the refinery process is less complex than the refinery process of Rönnskär in Sweden. It is assumed, that the gold doré-bars undergo the treatment of Wohlwill electrolysis (for details see 5.2.2.1, "Gold / Silver, secondary, from electronic scrap inecoinvent"). Due to the lack of specific data, the figure of refinement from electronic scrap is used: 1.63 kWh per kg gold (Renner et al., 2002a). No emissions were assumed, since on the one hand the high value of the processed material requires an efficient emission control and on the other hand, refinement is a hydrometallurgical process with low impact. The infrastructure is approximated with the facility of precious metal refinery. The unit process raw data are summarized in Tab. 5.67.

## 5. System Characterisation

Tab. 5.67: Unit process raw data of gold mining and refining in Tanzania

### 5.1.11 Data quality for primary gold / silver production

The datasets regarding the primary gold and silver production based mostly on environmental reports of mine corporations. Concerning energy, cyanide and explosive consumption, the data quality is good. Further material requirements have been estimated and scaled of Australian data by the production of gold.

Only a few companies show their emissions into air and water, thus in several of the country-specific datasets, emissions have been estimated by scaled ore. Information about tailings referred to Papua New-Guinea, where the only available data stems from. Therefore the data quality for emissions into air / water, as well as disposal of tailings is rather low.

A comparison of the datasets for gold and silver production on a country level can only be done with respect to the above mentioned limitations: A better performance of a country can be explained with better technology or with other assumptions on the emission level.

### 5.1.12 Primary gold, production mix (GLO)

These data sets describe an approximated average origin of gold. Shares of the different countries are specified in Tab. 2.2. No transports are considered, since these are included in the dataset “gold, at regional storage”.

site-chromium), horizontally aligned converter unit fed with hydrocarbon fuel, industrial oxygen and calcium oxide (Fig. 5.4, Davenport et al., 2002; Outokumpu, 2006).

Fig. 5.4 Detail of a converter unit (adopted from Davenport et al., 2002).

**Refining.** The processing of the electronic scrap in the Aisle converter is followed by a further refinement in a) the anode casting plant and b) the electrolytic refinery. At BOLIDEN's Rönnskär facility a new Twin M-16 anode casting facility (Fig. 5.5) is deployed to cast the hot blister copper into anodes. The facility consists of an inlet through which the hot blister copper is transported to the loader. Increasing the processing efficiency, the loader alternately feeds the blister copper into two wheel caster (Outokumpu, 2004).

Fig. 5.5 Sketch of a twin-wheel anode caster (adopted from Outokumpu, 2004) and the key infrastructure materials.

Once cast, the anodes are then finished and stored in the anode container. The anode sheets typically have a size of 1.00 m \* 1.40 m (approximated based upon Outokumpu, 2004) and consist of 99.5% copper including, however, impurities of sulphur, oxygen and traces of precious metals (Davenport et al., 2002). In the next step the copper anode is processed in the electrolytic refinery plant. This facility is a large hall with a large number of cells.

Fig. 5.6 Sketch of an electrolytic cell (adopted from Corrosion Technology International, 2006) and the key infrastructure materials

In 1999, the Rönnskär plant was equipped with 644 electrorefining cells and with 2 circulation tanks (Boliden, 2006c; Corrosion Technology International, 2006). The cells are made of stainless steel and reinforcement of glass fibre. The volume of the cells can vary considerably depending upon the process it is intended to be applied. The cells are continuously circulated by water spiked with copper, sulphuric acid and chloride (Davenport et al., 2002). Typically, the circulation time is about 0.02 m<sup>3</sup>/min and the power consumption ranges from less than 300 kWh/t material to nearly 400 kWh/t material (Davenport et al., 2002). The final products of the electrolytic step are copper and nickel. As a residual, precious metal containing anode slime is generated, which is finally treated in the precious metals plant in order to recover secondary gold, silver, palladium, and platinum.

**Anode slime treatment.** In a first step the precious metals containing anode slime is decopperised. The remaining residues are dried and processed by pyrometallurgical means. There also exists a hydrometallurgical route (Pesl & Anzinger, 2002). Whereas the pyrometallurgical route is apt to process large quantities of well defined anode slime from primary production, the hydrometallurgical route is more flexible to changes in feed composition as it occurs in the processing of slimes from secondary copper smelters. However, in Boliden the pyrometallurgical route is applied (Ludvigsson & Larsson, 2003). After de-copperising and precipitation of copper telluride the residue is dried and pyrolytically refined to silver rich dorée metal, which is cast into anodes for a subsequent electrorefining of silver (Moebius electrolysis) and Gold (Wohlwill electrolysis). The remaining slime consists mainly of PGM (platinum group metal) that is recovered.

Fig. 5.7 Diagram of pyro- and hydrometallurgical process routes for anode slime treatment (Pesi &amp; Anzinger, 2002).

Fig. 5.8 Sketch of the anode slimes treatment and precious metal recovery approach applied at Rönnskär (Ludvigsson &amp; Larsson, 2003).

### 5.2.1 Waste

The recovery of precious metals, such as gold, is associated with the generation of a number of by-products off-gases, sludge, slag, waste heat and dust (Umweltbundesamt, 2001). Most of the by-products are captured by appropriate filters (Umweltbundesamt, 2001). From an environmental perspective, most important, is the treatment of the residuals of the cyanide-containing sludge generated while concentrating gold from doré-grade gold. This sludge is treated applying sulphur-dioxide and air before it is dumped into tailing ponds (Boliden, 2002b). Concerning the other by-products and their treatment, no utilisable information could be compiled.

### 5.2.2 Emissions

Despite of the application of modern filter technologies, the precious metals recovery process is also associated with the generation of emissions to the environment (HELCOM, 2002). In particular the following emissions to air are considered problematic: dust, copper, lead, zinc, cadmium, arsenic, mercury, sulphur dioxide, nitrogen oxide, fluoride, chloride and PCDD/F. Emissions to water are include copper, lead, zinc, cadmium, arsenic, mercury (Mark & Lehner, 2002 and Umweltbundesamt, 2001)

#### 5.2.2.1 Gold / Silver, secondary, from electronic scrap in ecoinvent

No explicit LCA study covering the extraction of gold as secondary material from electronic scrap has been performed so far. As mentioned in the beginning of this chapter the recovery process of secondary gold is represented by the recovery of electronic scrap by integrated smelters as conducted by Boliden in the Rönneskär site. This inventory is solely based upon available industry information and literature data. In cases where no explicit gold recovery information was available, information on the extraction of copper was used as proxy.

The precious metals in the scrap traverse a lead smelting step ("Kaldo plant") and a subsequent conversion of the precious metals containing copper matte. The resulting blister copper is cast into anodes that are further refined, whereas the precious metals are transferred into the anode slime. The precious

metals are extracted from the anode slime in the final step. The production of secondary gold and silver therefore consists of a series of three consecutive multi-output datasets:

#### Secondary Copper Conversion

- lead, secondary, from electronic and electric scrap recycling, at plant
- metal values from electric waste, in blister-copper, at converter

#### Secondary Copper Refining

- PM from electric waste, in anode slime, at refinery
- copper, secondary, from electronic and electric scrap recycling, at refinery
- nickel, secondary, from electronic and electric scrap recycling, at refinery

#### Secondary Copper Precious Metal Refining

- silver, secondary, at precious metal refinery
- gold, secondary, at precious metal refinery
- palladium, secondary, at precious metal refinery

The meta information for these processes is compiled in Tab. 5.74, the reference flows for the multi-input processes are displayed in Fig. 5.10, Fig. 5.11 and Fig. 5.12.

Based on process descriptions and corporate reports a mass flow balance has herewith been established that serves as skeleton for the three models of the three multi-output processes (Fig. 5.9). The mixed feed of the copper refinery considered does not exclusively consist of electronic scrap. The intermediate reference flows “metal values from electric waste, in blister-copper, at converter” and “PM from electric waste, in anode slime, at refinery” therefore relate only to that part of the metals contained in the blister copper and the anode slime that is attributable to the electronic scrap in the input feed (Tab. 5.72). The reference flows do not reflect the intermediary, but the intended metals contained in the intermediary. This is reflected by the naming of these flows (in analogy to the naming of elementary flows), denoting the content and not the container.

Fig. 5.9 Mass Balance of the tree consecutive multi-output processes for Gold / Silver, secondary from electronic scrap. Mass is scaled to 1 kg gold output.

Tab. 5.72 Constituents of the intermediate reference flows in the system model (Fig. 5.9).

|                    | Scrap input                                 | into blister-copper                                               | To cathode copper                                                            | PGM in anode slime                                  |
|--------------------|---------------------------------------------|-------------------------------------------------------------------|------------------------------------------------------------------------------|-----------------------------------------------------|
| Corresponding flow | Electronic scrap, to secondary copper plant | metal values from electric waste, in blister-copper, at converter | copper, secondary, from electronic and electric scrap recycling, at refinery | PM from electric waste, in anode slime, at refinery |
| Mass               | 5882 kg                                     | 2159 kg                                                           | 1394kg                                                                       | 36 kg                                               |

### Allocation procedures

Based on the amount, the composition and the market prices of the materials involved, the burdens are allocated to the coupled reference flows based on their value (Tab. 5.73). The values contained were assessed according to the three years average from 2004 through 2006 based on USGS (2007).

**Tab. 5.73 Allocation of the burdens to the coupled multi-output reference flows according to their values depending on composition (Tab. 5.72) and the values (three years average from 2004 through 2006 based on USGS, 2007).**

|                                  | <b>\$ per kg</b> | <b>% wt product</b> | <b>% burden</b> |
|----------------------------------|------------------|---------------------|-----------------|
| lead, secondary                  | 1.15             | 4.2%                | 0.1%            |
| metal values from electric waste | 36.1             | 95.8%               | 99.9%           |

| General Comment to reference function | The multi-output-process "secondary copper conversion" delivers the two co-products "metal values from electric waste, in blister-copper, at converter" and "lead, secondary, from electronic and electric scrap recycling, at plant". The product "metal values from electric waste, ..." is an intermediary in the production of secondary gold from electric scrap and is not to be used by the LCA practitioner. The flow "lead, ..." is a by-product of this process that receives part of the burdens allocated. It must not be used to reflect lead. | The multi-output-process "secondary copper refining" delivers the three co-products "PM from electric waste, in anode slime, at refinery", "copper, secondary, from electronic and electric scrap recycling, at refinery", and "nickel, secondary, from electronic and electric scrap recycling, at refinery". The product "PM from electric waste, ..." is an intermediary in the production of secondary gold from electric scrap and is not to be used by the LCA practitioner. The flows "copper, ..." and "nickel, ..." are by-products of this process that receive part of the burdens allocated. They must not be used. | The multi-output-process "precious metal refining, secondary copper" delivers the co-products "silver, secondary, at precious metal refinery", "gold, secondary, at precious metal refinery" and "palladium, secondary, at precious metal refinery". The flows "silver, ..." and "gold, ..." are part of the global supply mix of gold and silver modelled in this part. The by-product "palladium, ..." receives its part of the burdens, but it is not aimed to be used by the data-user. |

## Secondary Copper Conversion

The energy and auxiliary requirements have been calculated on a per year basis from the respective patent and literature. 40'000 t annual electronic scrap treatment (Boliden, 2006c), 300 days actual annual operation time and 50 year service time were assumed to calculate process inputs and emissions per kg electronic scrap treated (Tab. 5.75). According to Boliden (2006c) and the assumed composition of the electronic scrap based on Motorola (2005), it can be calculated that 2.37% of the copper produced stems from electronic scrap (640 t of 27'000 t Pb per year) and 6.58% of the copper production, respectively (14'680 t of 223'000 t Cu per year). The Kaldo process uses the plastic in the scrap as fuel and as a reducing agent at the same time as organic compounds are oxidised. The caloric value in the electronic scrap is assumed to make up for the energy required to reduce the metals in the scrap. Therefore no additional demand in energy and oxygen is accounted for melting. For rotation of the furnace and ventilation in the converter electricity is required. No specific information was available. The electricity demand is stated in Boliden (2006c) to be 603 GWh per year for the whole site. Assuming an arbitrary share 5% that is attributable to the Kaldo plant, and disregarding the electricity for ventilation, 1.12 kWh per kg lead produced in the Kaldo furnace is calculated.

**Fig. 5.10 Unit process presentation of the converter step within the secondary copper plant. This multi-output process yields the flows “secondary copper conversion”.**

The arising slag is calculated from the content of ceramics in the scrap feed. Of the electronic scrap 31% consists of ceramics (Motorola, 2005). The yearly emissions for the converter aisle (“anode furnace” in source) and for the Kaldo plant have been taken from Umweltbundesamt (2001) and Mark & Lehner (2002), respectively. The distribution of differential PM classes have been adopted from copper smelting and amount  $PM_{<2.5} : PM_{2.5-10} : PM_{>10} = 3 : 2 : 1$  (CEPMEIP-Database, SNAP code 030304). The emissions have been allocated to electronic scrap processing according to their share in the production of lead and copper respectively (Tab. 5.75). The infrastructure is housed on an area of 1'200 m<sup>2</sup> (Boliden, 2000). The infrastructure was considered with the respective module “Facilities anode production, secondary copper” (Tab. 5.78). A service life time of 50 years and yearly production of 250'000 tons of combined copper and lead per year.

**Tab. 5.75** Emissions to air and water during the converter step. Respective Data for Kaldo plant taken from Umweltbundesamt (2001) and Mark & Lehner (2002) for converter aisle. Calculation bases on 27'000 t of lead and 223'000 t of copper, of which 2.37% and 6.58% originate from electronic scrap.

|                        |    | Kaldo    | Converter Aisle | Total                    |

## Secondary Copper Refining

In this multi-output process the cast anodes are refined by electrolytic refining. Based on the assumed constitution of the electric scrap a process flow balance was established (Fig. 5.11). Whereas the winning of cathode copper may be considered as the intended process, in the context of the secondary gold production the arising of anode slime is of importance. The process burdens are allocated to the three products anode slime, nickel sulphate, and cathode copper as described above. The values for the calculations are taken from Davenport et al. (2002).

**Fig. 5.11 Unit process representation of the electro refining step within the secondary copper plant. This multi-output process yields the three (main) flows “Precious metals (PM) from electric waste”, “copper, secondary” and “nickel, secondary”.**

The electrorefining consumes 320 kWh per t of copper cathode. An amount of 0.2 m<sup>3</sup> electrolyte per tonne is bled and purified for recycling into electrolytic refining. It is assumed that all of this volume is replenished with fresh electrolyte. The main constituent in the electrolyte is 180 kg sulphuric acid per m<sup>3</sup>. Other additives like HCl, bone glue, thiourea, and avitane are disregarded, since they all range from 20 to 100 g / m<sup>3</sup>. The 45 kg Copper per m<sup>3</sup> electrolyte is assumed to originate from the anode material or salts from within the operation. It is thus not inventoried. To heat the electrolyte from 20°C to 65 °C no additional energy requirements are assumed, since the electrolysis heats up the electrolyte. No heat recovery between circulations is assumed.

The data for the emissions (Tab. 5.76) originate from HELCOM (2002) and Umweltbundesamt (2001).

The infrastructure is reflected with the specific inventory (see section *Infrastructure for Secondary gold production*). There the lifetime production of the respective unit is said to amount to 6'900'000 t cathode copper output. The infrastructure requirements in this dimensioned according to the copper produced

**Tab. 5.76 Emissions to air and water during the refining of the copper anode. Respective data taken from Umweltbundesamt (2001) and Mark & Lehner (2002) Calculation bases on 223'000 t/a cathode copper and .**

| Emission               | unit | annual release | Per t cathode copper | per kg anode slime |

### Precious metal refining, secondary copper

The processing of anode slimes from secondary copper production takes place in four steps:

- Pressure leaching and Drying
- Smelting and converting of the residue
- Electrowinning of Silver
- Electrowinning of Gold

A diagram of the multi-output process is given in Fig. 5.12

**Fig. 5.12** Unit process representation of the precious metal refinery within the secondary copper plant. This multi-output process yields the flows “gold”, “silver” and “palladium, secondary, from electronic and electric scrap recycling”.

**Pressure leaching.** The slime is leached with electrolyte taken from the tankhouse under pressure (3-7 bar) and at elevated temperature of 115 °C. In Chen & Dutrizac (1990) we learn that the leaching can occur in a single stage for 5 h at 100 psi O<sub>2</sub> in a solution of 250 g/l H<sub>2</sub>SO<sub>4</sub> and 10% NaCl to prevent Ag from dissolution. This reduces the mass of the slime to 77% of the initial value. Assuming a volume of the leaching vessel of 10 m<sup>3</sup> and a reaction mass of 5 m<sup>3</sup> and a batch leaching procedure of 2'500 kg anode slime, 23 kg O<sub>2</sub> per batch or 0.00925 kg O<sub>2</sub> / kg slime are required. The sulphuric acid is assumed to originate from the electrolyte bleed and the NaCl is regarded not to be consumed by precipitation reactions. To heat up the 5'000 l electrolyte from 65 °C to 115 °C an additional 0.17 kWh/kg slime is needed, assuming 70% heat conversion efficiency.

**Drying.** 0.1 kWh electricity per kg are assumed to be required for drying.

**Smelting / Refining.** For fuel oil and requirements of oxygen as reducing agent the specific values for the conversion step in the Kaldo oven is taken as a proxy. Also the specific emission factors are taken (Kaldo furnace, Tab. 5.75) that derive from dividing the yearly emissions of the Kaldo furnace by the produced 27'000 t lead per year and scaling it to the metal produced by this process. According to Peterson & Lundquist (1977), the Kaldo process consumes 52.9 l oil and 123.5 Nm<sup>3</sup> of oxygen per tonne of charge (45% lead) or 4 MJ light fuel oil and 0.369 kg oxygen per kg lead bullion produced. These figures are multiplied with the total metal output of this inventory.

**Möbius electrolysis.** The silver concentration in the electrolyte is ca. 50 g/l. The free HNO<sub>3</sub> is 10 g/l and the anodic current density is 400 – 500 A/m<sup>2</sup>. The cell voltage is 2.0 – 2.5 V. The anodes and cathodes are usually arranged in parallel in the cell, and the energy consumption is ca. 0.6 kWh per kg of pure silver. To compensate for the anodically dissolved base metals that are not removed at the cathode (mainly copper), silver nitrate solution is fed into the electrolyte to prevent depletion of silver (Renner et al., 2002b). However, no additive consumption and replenishment of the electrolyte was considered. Likewise no emissions were assumed because of the purity and the high value of the material processed.

**Wohlwill electrolysis.** This process uses an electrolyte containing 2.5 mol/l of HCl and 2 mol/l of HAuCl<sub>4</sub> acid. Electrolysis is carried out with agitation at 65 – 75 °C. The raw gold is introduced as cast anode plates. The cathodes, on which the pure gold is deposited, were for many years made of fine gold of 0.25 mm thickness. These have now largely been replaced by sheet titanium or tantalum cathodes, from which the thick layer of fine gold can be peeled off. In a typical electrolysis cell, gold anodes weighing 12 kg and having dimensions 280×230×12 mm (0.138 m<sup>2</sup> surface) are used. Opposite to them are conductively connected cathode plates, arranged by two or three on a support rail. One cell normally contains five or six cathode units and four or five anodes. The maximum cell voltage [V] is 1.5 V and the maximum anodic current density [A] 1500 A/m<sup>2</sup> (Renner et al., 2002a). The South African Rand refinery (Auerswald & Radcliffe, 2005) gives a specific gold production rate of 0.2 kg per hour Wohlwill electrolysis. Assuming a current efficiency of 95% the energy consumption is [V] x [A] / 0.2 [kg/h] = 1.63 kWh per kg gold refined. No emissions were assumed because of the purity and the

high value of the material processed. The resulting sludge contains the PGM present in the electric scrap and is sold for further processing.

## 5. System Characterisation

Fig. 5.15 Flows for the multi-output process "secondary copper, precious metal refinery" and its representation in the ecoinvent database

## Infrastructure for Secondary gold production

This sub-chapter presents the datasets describing the facilities used in the production of secondary gold. For each of the three steps conversion, refinery, and precious metal plant a corresponding infrastructure inventory was established. The respective meta-data are shown in Tab. 5.77, whereas the flows and representations can be found in Fig. 5.16, Fig. 5.17 and Fig. 5.18. For more detailed description and use of the facilities refer to the previous process description in this chapter.

**Tab. 5.77** Meta information for the infrastructure in the production of secondary gold from electric waste.

| General Comment to reference function | Production of Kaldo converter and converter aisle: chromium steel, refractory bricks and concrete foundation. Building hall houses the facilities, covering 1200m <sup>2</sup> . Service lifetime 50 year, 250'000 t of metals produced per year. | Production of twin anode casting wheel and electrolytic cells: chromium steel, refractory bricks and concrete foundation. Building hall houses the facilities, covering 6'883m <sup>2</sup> . Service lifetime 30 years, yearly capacity of 230'000 t copper refined. | The precious metal plant is equipped as follows: 1 Electrolyte cell, 1 Elution cell, 5 Electrowinning cell, 1 Calcination furnace, 1 Smelting furnace, 1 Electrorefining cell. A building hall houses the equipment covering 5'000m <sup>2</sup> . The service life time assumed is 25 years, the yearly capacity of anode slime treatment is 243 t. |
| Start Date                            | 2002                                                                                                                                                                                                                                              | 2002                                                                                                                                                                                                                                                                  | 2002                                                                                                                                                                                                                                                                                                                                                 |

## Facilities copper conversion, secondary copper

For the furnaces a concrete foundation of 130 m<sup>3</sup> was assumed. The converter aisle and the Kaldo plant modelling was based on official commercial descriptions (Tab. 5.78). The housing was estimated to be 1'200 m<sup>2</sup> large, based on the corporate environmental report. The foundation was assessed with product descriptions to amount 130 m<sup>3</sup>, of which one third consists of exacting concrete, the rest of sole plate concrete. The disposal of the refractory lining is approximated with the disposal of nickel smelter slag. The steel is assumed to be recycled completely at the end of life of the facilities. Following the general modelling principles of ecoinvent, the steel therefore leaves the system burden-free and no disposal processes for steel are considered. The complete inventory is shown in Fig. 5.16.

**Tab. 5.78** Calculations for the infrastructure of the converter; 50 years service lifetime, 250'000 t production of total metals per year.

### Facilities anode refinery, secondary copper

This dataset comprises the anode casting unit and an array of 674 electrolytic cells with an estimated lifetime of 50 years and an annual copper production capacity of 230'000 t (Isaakson & Lehner, 2000). The anode casting unit (Fig. 5.5) and the electrolytic cells (Fig. 5.6) were herewith modelled based on official commercial descriptions (Tab. 5.79). The moulds of the anode casting wheels are lined with 0.002 m graphite. The walls of the electrolytic cells are made of stainless steel and reinforced with glass fibres. The disposal of the cell is approximated with the disposal of refractory. The steel is assumed to be recycled completely at the end of the facilities life time. Following the general modelling principles of ecoinvent, the steel therefore leaves the system burden free and no disposal processes for steel are considered. In the context of dataset's use within the production of secondary gold, 14'680 t blister copper from electronic scrap is yearly processed by the facilities.

**Tab. 5.79** Calculations for infrastructure of the anode refinery. 30 years service lifetime, 230'000 t copper per year.

### Precious metal refinery, secondary copper

This dataset describes the infrastructure operated in the precious metal refinery. The precious metal refinery stretches over 2'000 m<sup>2</sup> and houses following equipment: 1 pressure leaching vessel, 5 elec-

trourefining / electrowinning cells, 1 Kaldo furnace. The material consumption and disposal of the equipment is displayed in Tab. 5.80. The land use was assessed calculating with the 2'000 m<sup>2</sup> and the considered 25 year life time.

The electrowinning cell was reflected with the required steel for the vessel, the production of the steel wool (electrode, approximated with wire drawing) and a lead electrode, according to a operation for copper electrowinning described in Davenport et al. (2002). The other equipment parts have been materialised based on estimations and datasheets of the producer. The steel is assumed to be recycled completely at the end of the facilities life time. Following the general modelling principles of ecoinvent, the steel therefore leaves the system burden free and no disposal processes for steel are considered. The facilities produce 243 tonnes precious metals – silver, gold and palladium – per year.

**Tab. 5.80 Calculations for equipment of the precious metal plant. 25 years service lifetime, 243 t PM per year.**

### 5.2.3 Data quality

Data uncertainty is derived using the Pedigree matrix as described in Frischknecht et al. (2004). The uncertainty for the inventory items related to the Kaldor process and the conversion are underestimated by the Pedigree approach, therefore the standard deviation of the flows is set to 5 to reflect their speculative nature. As there was only a limited access to information of the industry and as data partly dated back more than ten years ago, the reliability and correctness of the data set is limited. Due to limitation in time for this LCI study, only the Boliden process for the production of secondary gold was analysed. That may further limit the explanatory power when it comes to LCA studies of products where the production of secondary gold becomes important. However, since the concentration of precious metals in the electronic scrap feed is high compared to natural ores, the resulting exchanges related to the production of secondary gold and silver are low compared to gold and silver from ores. Therefore the quality is sufficient for the use as background data in a supply mix of primary and secondary gold.

## 5.3 Production of Silver from Lead-Zinc ores

Today, the silver in bullion lead, together with gold and platinum metals, is concentrated by the Parkes process. The process involves the production of a solid alloy of lead, zinc, and silver by stirring zinc into molten impure lead. On cooling a crust is formed that floats on the surface of the molten metal (450 °C) where it is skimmed off (Renner et al., 2002b). The composition of this crust is determined by the laws of solid solution of the ternary alloy system Ag-Pb-Zn. The composition of the crust lies between 5 to 10% Ag, 15 to 30% Zn, the remainder being lead with a small amount of oxygen and other contaminants such as copper (Evans et al., 1993). Reuter (2005) indicates in the calculations made a composition of 18% Ag, 43% Zn with 38% lead, and 1% antimony. This so-called parkes de-silvering crust is processed to raw silver by following steps:

- The adhering liquid lead is removed by **hot pressing**.
- The zinc is distilled in a **retort or vacuum furnace**. The residue consists of a lead – noble-metal alloy with up to 50 % silver, ca. 1 % zinc, and some copper, arsenic, antimony, and bismuth.
- It is **oxidized by cupellation** to obtain crude silver and oxidised lead (litharge) with remaining contaminants.
- The resulting raw silver is electrolytically refined (electrorefined) by the Möbius electrolysis.

### 5.3.1 Silver from lead production in ecoinvent

No explicit study was available that covers the life cycle inventory of the production of silver from lead. Thus this inventory is solely based upon available information from literature. In cases where no explicit silver recovery information was available, information on the refining of zinc and lead was used as proxy.

The meta information for these processes are compiled in Tab. 5.81, the reference flows for the multi-input processes are displayed in Fig. 5.19.

Tab. 5.81 Meta information for the production processes of silver from lead production.

### Raw and auxiliary materials, waste

Assuming a silver concentration in the Parkes crust of 18% and an overall recovery yield of 97.3% (Reuter, 2005) an amount of 5.77 kg crust is fed to obtain 1 kg refined silver.

To form a Parkes crust, zinc is stirred into the molten lead. This added zinc however goes to 97% to the lead that is pressed out of the Parkes crust and is returned to the lead processing. The remainder is recovered to 98.2% by vacuum distillation and is returned to form the Parkes crust. Only the remaining 1.8% reports to the intermediate litharge (Reuter, 2005). All the intermediate products as well as the litharge are returned into the process. No further auxiliary materials such as fluxing agents are considered. All employed materials are supposed to be recycled into the production process, therefore no waste fraction is considered.

### Energy demand

Electricity demand for the different process stages is reported in Reuter (2005) per kg silver as follows: Vacuum Distillation: 1.44 kWh; Cupellation: 4.53 kWh; Moebius Electrolysis: 0.60 kWh.

### Process emissions

Rentz et al. (1999) report process emissions related to different processes in the lead and zinc industry in Germany. Since no emission factors for the silver production are available, values for comparable best available technologies (Remelting plant and New Jersey Retort) are taken as approximation. The distribution of differential PM classes have been adopted from copper smelting and amount PM<sub><2.5</sub> : PM<sub>2.5-10</sub> : PM<sub>>10</sub> = 3 : 2 : 1 (CEPMEIP-Database, SNAP code 030304). No emissions to water are considered.

### Transport and infrastructure

Since the parkes crust is supposed to be processed on site and only a small part of the feed is assumed to be acquired from supply external to the facility, no transports of the feed are considered. The infrastructure is reflected with the generic dataset for a metal smelter that is based on inventories from aluminium and iron industry. Lifetime: 50a, output: 2'650'000 t metal per year, reporting to the total amount of silver, zinc and lead intermediate produced.

**Tab. 5.82 Emissions to air from parkes crust processing. Approximation from BAT processes in German Zinc industry (Rentz et al., 1999), geometric mean of the lowest and highest value.**

| Emission to air | CBAT Remelting plant | CBAT New Jersey Retort | low                 | high                | geometric mean (this study) |

| Pb              | 2 - 8                | 6                      | 2                   | 8                   | 4                           |

### 5.3.2 Data quality

The emissions are approximated with generic processes in zinc and lead production. Data uncertainty is derived using the Pedigree matrix as described in Frischknecht et al. (2004). Quality is sufficient to figure as part in the supplymix of silver.

## 5. System Characterisation

## 5.4 Production of silver and raw copper telluride from copper ores

No explicit study covering the extraction of silver as by-product from copper production could be found. This inventory is based on available industry information and literature data.

The processing of anode slimes from copper production takes place in four steps:

- Pressure leaching of slimes
- Precipitating of copper telluride from solution
- Drying, smelting and converting of the residue
- Electrowinning of silver

In the decopperising leaching process of copper refinery slimes, a considerable amount of tellurium dissolves (70-80% and 95% under atmospheric pressure leaching and pressurized leaching, respectively). The precipitation of telluride is done by copper choppings that are arranged in a column. The leach solution is led through the column and telluride precipitate on the surface (Shibasaki et al., 1992). Fig. 5.20 shows the process as done in Mitsubishi's Naoshima refinery.

Fig. 5.20 Processing of anode slimes to retract silver and tellurium at Naoshima refinery, Mitsubishi Materials Corp. (Shibasaki et al., 1992).

### 5.4.1 Processing of anode slime, primary copper production, in ecoinvent

This module consists of a multi-output dataset (see Fig. 5.22 and Tab. 5.83). The multi-output-process "processing of anode slime, primary copper production" delivers the two co-products "copper-telluride

cement, from copper production" and "silver, from copper production, at refinery". The product "copper-telluride cement, ..." is an intermediary in the production of telluride and is not intended to be used by the LCA practitioner. The flow "silver, ..." is a by-product of this process that receives part of the burdens. It must not be used to reflect silver. For silver and telluride, please refer to the respective adequate datasets.

The raw anode slime is inventoried by the by-product dataset "anode slime, silver and tellurium containing, primary copper production" (Fig. 5.21). The slime represented contains 20% Silver and 3% Tellurium which in turn reflects the coupled production ratio of silver and tellurium from copper production industry on a global average (see Part III "Copper" in this report).

**Fig. 5.21** Model overview and interrelation of silver production with copper extraction. For detailed information see Part III "Copper" in this report.

The anode slime processing corresponds to a part of similar processes described in the chapter 5.2.2.1 Gold / Silver, secondary, from electronic scrap in ecoinvent. Hence, the respective values are adapted for the processing of silver and telluride containing slimes.

**Tab. 5.83** Meta information for the production processes of silver from copper production.

| General Comment to reference function | The multi-output-process "processing of anode slime, primary copper production" delivers the two co-products "copper-telluride cement, from copper production" and "silver, from copper production, at refinery". The product "copper-telluride cement, ..." is an intermediary in the production of telluride and is not to be used by the LCA practitioner. The flow "silver, ..." is a by-product of this process that receives part of the burdens allocated. The data set must not be used to reflect silver! For tellurium and silver the respective, adequate end-user datasets have to be chosen. |

**Pressure leaching.** The slime (5 kg) is leached with electrolyte taken from the tankhouse under pressure (3-7 bar) and at elevated temperature of 115 °C. From Chen & Dutrizac (1990) we learn that the

leaching can occur in a single stage for 5 h at 100 psi  $O_2$  in a solution of 250 g / l  $H_2SO_4$  and 10% NaCl to prevent Ag from dissolution. This reduces the mass of the slime to 77% of the initial value. Assuming a volume of the leaching vessel of 10 m<sup>3</sup> and a reaction volume of 5 m<sup>3</sup> and a batch leaching procedure of 2'500 kg anode slime, 23 kg  $O_2$  per batch or 0.00925 kg  $O_2$  / kg slime are required (see calculations in 5.2.2.1 *Gold / Silver, secondary, from electronic scrap in ecoinvent*). The sulphuric acid is assumed to originate from the electrolyte bleed and the NaCl is regarded not to be consumed by precipitation reactions. To heat up the 5'000 l electrolyte from 65 °C to 115 °C an additional 0.17 kWh/kg slime is needed, assuming 70% heat conversion efficiency. A process efficiency of 90% is assumed, the rest of the Tellurium reports to the residual solution.

**Precipitation.** The copper telluride is precipitated from the leach solution by solid copper. This precipitation – or stripping – is spontaneous given the optimal reaction time. Hence only the metallic copper choppings are accounted for, that are used to strip the raw copper telluride. They are contained in the produced raw copper telluride by 50%<sub>wt</sub>.

**Drying.** 0.1 kWh electricity per kg dry product is assumed to be required for drying.

**Smelting / Refining.** For fuel oil and requirements of oxygen as reducing agent the same specific values as for the conversion step in the Kaldo oven is taken as a proxy. Also the specific emission factors are taken (Kaldo furnace, Tab. 5.75) that derive from dividing the yearly emissions of the Kaldo furnace by the produced 27'000 t lead per year and scaling it to the metal produced by this process. According to Peterson & Lundquist (1977), the Kaldo process consumes 52.9 l oil and 123.5 Nm<sup>3</sup> of oxygen per tonne of charge (45% lead) or 4 MJ light fuel oil and 0.369 kg oxygen per kg lead bullion produced. These figures are multiplied with the total metal output of this inventory. Eventual electricity consumption for furnace operation is assumed to be low and therefore is disregarded in this step.

**Möbius electrolysis.** The silver concentration in the electrolyte is ca. 50 g/L. The free  $HNO_3$  is 10 g/L and the anodic current density is 400 – 500 A/m<sup>2</sup>. The cell voltage is 2.0 – 2.5 V. The anodes and cathodes are usually arranged in parallel in the cell, and the energy consumption is ca. 0.6 kWh per kg of pure silver. To compensate for the anodically dissolved base metals that are not removed at the cathode (mainly copper), silver nitrate solution is fed into the electrolyte to prevent depletion of silver (Renner et al., 2002b). However, no additive consumption and replenishment of the electrolyte was considered. Likewise no emissions were assumed because of the purity and the high value of the material processed.

**Allocation procedure.** The allocation of the subprocesses copper telluride and silver formation is not evident to solve, since only the final commodity prices are known but no in-firm price for the CuTe cement, on which the allocation would rely. Also the share of the products in total costs (gross sales method as proposed in Guinée et al. (2004) and Guinée et al. (2001)) is not easy to estimate. The by-product allocation problem – the joint production of silver and copper telluride – is reduced here by a subdivision of the sub-processes (according to Ekvall & Finnveden, 2001). The tellurium production from the raw copper telluride is treated in a distinct inventory. Hence it is the task to allocate the burdens between the silver and the CuTe cementate, whereas for latter no published price is available.

As starting point for an estimation it is assumed that the profit margin for the production of copper telluride cement corresponds to the company's performance. Taking an arbitrary performance value of 10% - which reflects the general profit expectations of major enterprises – the value of the cement corresponds consequently to 10% of the proceeds from sale of copper telluride. Therefore 10 % of the copper telluride price is taken to estimate the value of the cement.

The composition and the corresponding values in the by-products result in a split of 8% to the copper telluride cementate and 92% to the silver (Tab. 5.84). The values contained were assessed according to the three years average from 2004 through 2006 based on USGS (2007).

Tab. 5.84 Allocation factors for copper telluride and silver using economic criteria.

| Reference flows                |    | Amount | \$ / kg | Value | Split |
|--------------------------------|----|--------|---------|-------|-------|
| Copper Telluride, by-product   | kg | 0.0489 | 7.57    | 0.370 | 8%    |
| Silver, from copper production | kg | 1.0    | 4.48    | 4.48  | 92%   |

### 5.4.2 Data quality

The dataset bases to large parts on extrapolations and approximations. Data uncertainty is derived using the Pedigree matrix as described in Frischknecht et al. (2004). The uncertainty for the inventory items related to the Kaldo process and the conversion are underestimated by the Pedigree approach, therefore the standard deviation of the flows is set to 5 to reflect their speculative nature. However, the dataset is sufficient to serve as upstream process of silver and telluride used in background data. The dataset must not be used to make assertions regarding different refining processes.

## 5. System Characterisation

## 5.5 Gold, at regional storage

A large amount of gold is obtained from secondary materials. Renner et al. (2002a) estimates that around 50% of the world gold supply originates from secondary production. The world mine production in 2005 has been 2'518 tonnes, the supply of gold from scrap was reported to be 0.9 tonnes, or 26%<sup>10</sup>. GFSM reports for 2006 an increased scrap supply (1'100 tonnes) while the mine production dropped to 2.44 tonnes. (minus 3%), which corresponds to a secondary supply of 31%. In this inventory a share of 30 % secondary production is assumed.

Today, small-scale mining might account for one-quarter of the world gold output<sup>11</sup>. However, these processes were not inventoried in this study due to lack of information.

Fig. 5.23 World mine production (Data: GFSM).

A default distance of 250 km from the refinery to the airport and 250 km further to the regional dealer is assumed. Transport distances are estimated on bee-line measures (see Tab. 5.85) and reflect the mine production mix in Tab. 5.69. The resulting inventory is displayed in Fig. 5.25

## 5.6 Silver, at regional storage

This dataset represents the use of silver in Europe. The total mine production in 2005 amounted to 70% of the demand, whereas 21% of the silver was obtained from secondary sources (scrap), 7% from governmental sales and 2% from hedging (Klapwijk et al., 2006).

For primary production, only silver production as by-product from lead / zinc, copper, and gold extraction is available in the ecoinvent Database. These supply sources contribute for 76% of the total primary supply which is regarded sufficient to reflect the production of silver on a global scale. The shares of the available sources (lead/zinc, copper, gold) are scaled for the respective dataset to 100% (see Tab. 2.3). No detailed statistics on silver import to Europe was available, the transports of the primary silver are estimated on the supply statistics provided by the silver institute on a global average

(Tab. 5.85). A default distance of 250 km from the refinery to the airport and 250 km further to the regional dealer is assumed. The resulting inventory is displayed in Fig. 5.24.

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1

---

## Comments on version 2.1

This version corresponds to version 2.0 with changes of the errors detected in the meantime.

The cadmium emissions to air were too high due to a mistake regarding the filtration of airborne emissions in the cadmium purification process. The correct values are given in Tab. 1.

**Tab. 1**      **Corrected values of cadmium emissions ( to air/high population density) of the “cadmium, semiconductor grade” datasets**

| Dataset ID | Name                                                       | Value in ecoinvent Data v2.01 | Correct value | Unit  |
|------------|------------------------------------------------------------|-------------------------------|---------------|-------|
| DS-ID 6902 | cadmium, semiconductor-grade, at plant, US, [kg];          | 1.62E-04                      | 6.0E-06       | Kg/kg |
| DS-ID 6905 | cadmium chloride, semiconductor-grade, at plant, US, [kg]  | 4.4572E-5                     | 3.876E-06     | Kg(kg |
| DS-ID 6906 | cadmium telluride, semiconductor-grade, at plant, US, [kg] | 1.5E-5                        | 6.0E-06       | Kg/kg |

The waterborne cadmium emissions in the dataset “cadmium sulphide, semiconductor-grade, at plant, US, [k]”are mismatched as “from nature”. However, they are emissions “to nature”.

# 1 Introduction

Several metals feature semi conductive behaviour. For this they have to be purified to a high degree and arranged in layers onto a carrier. This part describes the extraction and purification of some of the most important semiconductor materials:

- Tellurium *raw material from copper production (part III)*
- Gallium, semiconductor grade *raw material from aluminium production (part I)*
- Cadmium, semiconductor grade *raw material of lead-zinc production (part VIII)*
- Cadmium Telluride, semiconductor grade *raw material of lead-zinc production (part VIII)*
- Cadmium Chloride, semiconductor grade *raw material of lead-zinc production (part VIII)*
- Cadmium Sulphide, semiconductor grade *raw material of lead-zinc production (part VIII)*

The raw materials for these metals often are by-products of base metal production. For information on these, please refer to the respective part within this report.

## Tellurium

### Acknowledgement

We thank Vasilis Fthenakis and Olliver Krahl for the information provided in a personal communication.

### 2.1 Introduction

Tellurium (CAS-Number: 13494-80-9) is a metallic element that is often extracted as a by-product of processing copper, lead, gold, and bismuth ores. Tellurium has 8 natural stable isotopes and some 21 additional artificial unstable isotopes are known (Knockaert (2002)). A Hungarian scientist discovered tellurium in 1782. For a long time, only minor amounts were extracted. One reason for the increasing demand of tellurium is the application in the new field of thin film solar cells. Other common applications are thermoelectric devices and as an alloy for the production of free-machining steel.

### 2.2 Reserves and resources of tellurium

The main source of tellurium is the copper anode slime, which is a by-product of the electro winning-process from copper-treatment (Fthenakis (2004)).

The principal source of tellurium is anode sludge, produced during the electrolytic refining of blister copper. Tellurium is produced mainly in the United States, Canada, Peru and Japan. The recovery of tellurium from secondary materials accounts for 10-20% of world tellurium production. As copper ores are the main sources for tellurium, public statistics are based on the copper industry. The following numbers are from the former “United States Bureau of Mines” and are an estimation about the reserves, based on a fixed recovery factor of 0.065 kg Te per tonne of copper (Knockaert (2002)).

According to Fthenakis (2000) a recycling of the metals from the thin-film solar cell can be done, but is not accounted here.

### 2.3 Characterisation of tellurium

Tellurium is a relatively rare element, in the same chemical family as oxygen, sulphur, and selenium. Tellurium has a metallic glance in its pure state, and is relatively soft (Knockaert (2002)). For a long time, it was more a waste-product of metallurgy, than a raw material for industrial purposes.

## 2.4 Use and application of material

According to Georg (2004)) there are two main producers of refined tellurium. One is ASARCO from the United States and the other is Umicore in Belgium. Guilinger (1999d) states a list of 29 producers all around the world that fabricate three different categories of tellurium:

- tellurium dioxides – sludge and precipitates of variable purity around 35%
- commercial grade tellurium (99.7% purity)
- high purity tellurium (99.9% to 99.9999%)

The world production per year is in the range of 200 to 300 metric tons. Knockaert (2002) states a broad trade of concentrate, blister and anode copper. This complicates a detailed estimation about the global refinery production. The different market sectors are given in Georg (2004). Some further details are described below:

- Improvement of steel by addition of small quantities of tellurium (up to 0.1%), It helps to control the chill depth of rapidly cooled surfaces and produces hard, wear-resistant top layers.
- Tellurium is used in combination with other components in many catalysts (chemical reactions: oxidation, ammonisation, (de-) hydrogenation, (de-) halogenations, etc.)
- In electronics, tellurium is a well-known additive in selenium-photoreceptors. Tellurium increases the sensitivity and broadens the spectral response of the photoreceptor.
- Polycrystalline cadmium telluride is used in photovoltaic solar cells; CdTe has a direct band gap of 1.5eV and a high optical absorption coefficient.

Tab. 2.3 Market share of tellurium (data for United States), Source: Georg (2004)

|                                                                        |      |
|------------------------------------------------------------------------|------|
| Alloying element to improve the properties of iron and steel           | 40%  |
| Catalyst and chemicals                                                 | 24%  |
| Photoreceptors and thermoelectric devices                              | 22%  |
| Additive to non-ferrous-metals                                         | 8%   |
| Digital video discs and other minor uses (incl. thin-film solar cells) | 6%   |
| Total                                                                  | 100% |

The price for tellurium has increased rapidly in the last 2 years, mainly due to the increased demands from China and solar cell manufacturers worldwide. In November 2004 the price was about US\$ 50 per kilogram (Georg (2004)). In 2005 the price ranged from US\$ 110 to US\$ 150 per kg tellurium (Metal Bulletin (2006)), respectively US\$ 100 to 140 US\$ according to PPM Pure metals.<sup>1</sup> Knockaert

<sup>1</sup> Personal communication: Olliver Krahle, PPM Pure Metals GmbH, Germany (24<sup>th</sup> of January 2007)

(2002) reports that tellurium 99.99% (4N) is normally 40-50% more expensive than tellurium 99.9% (3N) and tellurium 99.999% (5N) is more than double price of the standard-grad tellurium (3N).

## 2.5 Production process

This part is mainly based on the information of Knockaert (2002) and Fthenakis (2004). After pyrometallurgic separations and electrolytic refining, the copper can be collected on the cathode with a purity of 99.95%. The metallic impurities form the anode slime, which is the main source for the production of tellurium (Fthenakis (2004). Further details and information about the copper process can be found in the corresponding section of this report.

The slime contains tellurium, beside various metals like Bi, Sb, Se, Pb, Au, Ag, As or Ni (see Tab. 2.4.). Therefore, the separation process is usually done for all metals at one place. Fig. 2.1 shows an example of a flow sheet for anode slime treatment.

Fig. 2.1 Example flow sheet for anode slime treatment, Source: IPPC (2001)

The tellurium content in the copper varies. The mentioned “United States Bureau of Mines” estimates an average tellurium content of about 0.065 kg per ton of copper (Knockaert (2002)). The tellurium content in the sludge varies from 0.5% to 10%. Three copper-producers stated a typical tellurium concentration of 2%, 3.2% and 3.64%, with a geometrical mean of 2.85% (Tab. 2.4).

As the tellurium is separated from the slime as copper-telluride-cementate, the life cycle assessment starts with the separation of tellurium from the cementate, the Pre-treatment is not assessed in this dataset. The following processes are considered (see also Fig. 2.2):

- (i) Dissolving of copper-cementate with sulphuric acid
- (ii) Electrolysis of tellurium from the solution
- (iii) Purification of cathode-tellurium with Zone melting

Fig. 2.2 Production process of tellurium

**Dissolving cementate and electrolysis:** The cementate of copper-telluride is treated with sulphuric acid. The next step is the electrolysis of the solution to extract the tellurium at the cathode. Further details and chemical reactions can be found in Knockaert (2002).

**Purification:** According to Fthenakis (2004), high purity tellurium is produced by electrolytic purification and subsequent melting and atomization or by vacuum-distillation. According to industrial sources in the mentioned report, electrolytic purification does not produce any emissions and all waste is recycled. On the other hand, it is mentioned that for the production of 0.6 kg tellurium (99.999% or 5N) 0.75 kg tellurium (99.99% or 4N) is required.<sup>2</sup> This represents a tellurium loss of 20% during this phase of purification.

## 2.6 Life cycle inventory

No LCA-study on tellurium production is available<sup>3</sup>. This module is based on reported values from Knockaert (2002) and (Fthenakis & Kim (2005); Fthenakis (2004)). The functional unit of this process is 1 kilogram of tellurium with a purity of 99.999% (5N). This purity allows a direct use for the production of solar cells and electronic devices. This dataset describes the production and purification of tellurium in Europe, starting from the anode sludge from copper purification.

**Transports:** Knockaert (2002) reported a wide trade with concentrate, blister and anode copper, so an average transport distance of 4000 km by ship was assumed for the anode slime with a 3% concentration of tellurium. The allocation for this transport was done by weight (see Tab. 2.4). The transport to the plant was assumed with standard transport distances.

**Demand in materials and energy:** The input feed is copper-telluride cementate, that is derived from the primary copper production cycle (See Part “Copper” in the corresponding chapter). The telluride

<sup>2</sup> Personal communication: Email from V. Fthenakis to N. Jungbluth, Nov. 2006

<sup>3</sup> Steinberger (1997) analysed the life cycle of CdTe-solar cells, though the assumptions for the production and purification of tellurium were too rough. Therefore no data from the mentioned thesis has been used.

content in the cementate is 50% (Shibasaki et al. 1992), an overall process yield of 90% is assumed. The arising copper rich solution is recycled to the copper electrowinning cells and leaves the system burden free.

During the process of leaching, for each tonne of copper-telluride 150 kg of H<sub>2</sub>SO<sub>4</sub> (25%) is used (Davenport et al. 2002). The demand of energy is reported by Fthenakis (2004). It is assumed, that the energy carrier is electricity. Since there is no specific process-data available for the tellurium production, the data from the corresponding chapters about the hydrometallurgical zinc-production was taken instead for water-use. However, the uncertainty is fairly high.

**Emissions:** Fthenakis (2004) states that “emissions in hydrometallurgical / electrolytic plants are likely to be negligible unless the sulphuric-acid tanks are open to the atmosphere.” For emissions, proxy-data of zinc-production has been used: Assuming a production with 50% open tanks, a value of 9.55g sulphuric acid per kg tellurium was chosen (Xiao et al. (2003), cited in the chapter about zinc-production)

**Infrastructure:** The infrastructure of a chemical plant, organics has been taken as an assumption with the mentioned output of 50'000 tons per year and a lifespan of 50 years.

|                    | GeneralComment             | This datasets describes the production of high-grade tellurium (99.999%) from copper-telluride cementate by hydrometallurgical processes. These hydrometallurgical processes are the dissolving of copper-telluride cementate with sulphuric acid, the following electrolysis and subsequent purification with zone-melting. This purity of tellurium can be used in the production of thin film solar cells. |

## 3 Gallium, semiconductor-grade

### 3.1 Introduction

Gallium (CAS-Number: 7440-55-3) is a metallic element, similar in many characteristics to aluminium. Gallium is an excellent conductor of heat and electricity and has a melting point of 29.8° C. It can be extracted from bauxite ore by several different processes. Gallium is widely used in the field of optoelectronics (e.g. LEDs), telecommunication, aerospace and many commercial and household items such as alloys, computers and DVDs (Moskalyk 2003).

### 3.2 Resources and production of gallium

Gallium is widely spread on Earth, but is rarely found in concentrations greater than 0.1%. Gallium-containing minerals do not have an economic significance. Gallium can be extracted as a trace component in bauxite, coal or several minerals. Gutiérrez et al. (1997) investigated the extraction of gallium from coal fly ash from power plants. Occasionally, high concentrations of gallium are found in association with polymetallic deposits (e.g. copper, zinc, silver).

However, the dominant world production of gallium is as a by-product from the production of aluminium oxide. Most gallium is recovered from the crude aluminium hydroxide (Guilinger 1999c). The U.S. Geological Survey estimates the world gallium reserves in known reserves of bauxite (concentration of 50 ppm) and zinc ores of about 1 million-ton gallium. France is the largest producer of refined gallium in the world (Moskalyk 2003).

### 3.3 Characterisation of gallium

Before its discovery, most of the properties of gallium have been predicted and described by Mendeleev on the basis of its position in his periodic table. The French Lecoq de Boisbaudran discovered

<sup>4</sup> Estimation (based on the world production in 2005 of 63 tons of gallium, assuming that each enterprise has the same ratio of production / production capacity)

gallium spectroscopically in 1875 (Latin *Gallia* meaning Gaul, essentially modern France) (Guilinger 1999c).

### 3.4 Use and application of material

About 95% of the gallium consumed annually (57 t) is in the form of gallium arsenide (GaAs) compounds, which are used in optoelectronic devices (e.g. LEDs = light emitting diodes, laser diodes, photo detectors and solar cells) or in integrated circuits. The current price for 1 kg gallium of 99.9999% purity was at the end of the year 2005 about 512 US\$ (Kramer 2005).

**Tab. 3.3 Market share of gallium in United States, Source: Kramer (2005)**

|                                        | Gallium (kg) | %     |
|----------------------------------------|--------------|-------|
| Optoelectronic devices                 |              |       |
| Laser diodes and light-emitting diodes | 3880         | 20.6% |
| Photo detectors and solar cells        | 219          | 1.2%  |

### 3.5 Production process

#### 3.5.1 Extraction from aluminium oxide liquor

This part is mainly based on Greber (2005) and Kramer (2005). The most important process for gallium production is the extraction of the metal from the Bayer liquor in aluminium oxide plants. The liquor contains 70 – 150 mg / litre of gallium, depending on the bauxite and the concentration of the caustic liquor. Selvi et al. (2004) reported a typical Bayer liquor as shown in Tab. 3.4.

Tab. 3.4. Composition of Bayer liquor, according to Selvi et al. (2004)

|                         |                        |
|-------------------------|------------------------|
| Sodium Hydroxide (NaOH) | 220 g / litre          |
| Aluminium               | 60 g / litre           |
| Gallium                 | 145 mg / litre         |
| Vanadium                | 130 mg / litre         |
| Viscosity               | 5.75 Cp (at 28°C)      |
| Specific Gravity        | 1.35 g/cm <sup>3</sup> |

The gallium extraction plant is usually located within or very near to the aluminium oxide plants. Fig. 3.1. shows the gallium extraction within the chain of aluminium production.

Fig. 3.1 Flow diagram showing gallium extraction by Rhône-Poulenc-Process, Source: Greber (2005)

Three types of processes are mainly used to extract the gallium. Below is a short summary of each process. A description in more details can be found in Greber (2005) and Power Porto (1990).

(1) **extraction with chelating agents (the Rhône-Poulenc-Process)**

In 1974, it was discovered, that hydroxyquinolines could be used to extract gallium from sodium aluminates liquors. The aluminate liquor is brought into contact with a solution of Kelex 100<sup>5</sup> in kerosene. Gallium is thereby extracted from the liquor along with aluminium and sodium. Most of the aluminium and sodium is scrubbed from the extraction by a treatment with dilute acid. The gallium itself is then stripped with concentrated sulphuric acid. The metal can be isolated from this concentrate by direct electrolysis. Although the process solutions are recycled, considerable quantities of waste acid is generated (Greber 2005). 35 to 40 tons of gallium is produced via this route.

(2) **electrolytic processes (the Alusuisse-Process)**

The electrolytic process depends on the fact that mercury forms an amalgam with gallium

<sup>5</sup> Kelex100 is a well-known solvent extraction product, chemical name: 7-(4-ethyl-1-methyloctyl)quinolin-8-ol CAS-Number: 29171-27-5

from which the gallium may be extracted with a caustic soda solution. The mercury is recycled to produce again sodium amalgam. Hence the mercury circulates in a closed system. This process requires special conditions to reach economically acceptable values (like > 150 g/l sodium and very low concentrations of vanadium, tungsten and molybdenum). The environmental problems associated with mercury further discourage the use of electrolytic processes.

**(3) fractional precipitation (the P  chiney-Process)**

The gallium-containing sodium aluminate solution is treated with carbon dioxide to precipitate its pure aluminium hydroxide. This increases the gallium content of the liquor. Further treatment with fractional precipitation is used to separate the gallium. Finally metallic gallium is obtained by electrolysis. This process is labour and energy-intensive. China produces gallium by this process.

Izumi (2004) describes some laboratory-scale processes about the re-extraction and recycling of gallium from electronic scrap. However, no recycling processes are taken into account since there is no data available.

Since the Rh  ne-Poulenc-Process dominates the production and is the least-cost effective, the focus of the following life-cycle inventory was set on this process (Moskalyk 2003).

### **3.5.2 Purification**

Different procedures can be used to remove the impurities such as mercury and zinc:

- vacuum distillation
- washing with aqueous acids and alkalis
- fractional distillation of liquid gallium compounds
- fractional crystallization
- single crystal growth

The purest gallium is obtained by fractional crystallization (Meijer et al. 2003) or single crystal growth with a purity of 99.999999% (Power Porto 1990). The fractional crystallization process purifies a raw gallium material utilizing segregation. Since solid gallium is lighter than liquid gallium, the solid gallium floats in the form of a small mass on the surface of the liquid gallium. Seed crystals are present in a melted raw gallium material and at surface. The melted raw gallium material is cooled with a gas to a temperature less than its melting point. The gallium material is then solidified on the seed crystals as nuclei with unidirect solidification (Maeda & Kadokura 1993). Bautista (2003) gives an overview about the different purification methods.

## **3.6 Life cycle inventories**

### **3.6.1 Gallium, in Bayer liquor from aluminium production, at plant**

The production process of gallium starts from the liquid and crystallized Bayer-Liquor. Although there is a production capacity of 160 t available, only 60 t are produced annually. This indicates a low economic interest of gallium production at the moment. Therefore, no upstream processes are taken into account. This is in line with the proposed methodology of (Guin  e et al. 2004).

### **3.6.2 Gallium, semiconductor-grade**

**Production (Accumulation):** The following data from Bautista (2003) is from a laboratory-scale installation. Selvi et al. (2004) reports that chelating agents can be reused more than 30 times in laboratory scale installations. In other settings (different types of chelating agents) more than 10 cycles have been found. This study assumes, that the chelating agent (Kelex 100) can be used 30 times and other

organic solvents can be re-used for one year. Since the average production is about 3.9 t per company and year, the calculation has been made with a recycling-rate of 3900 times at a production rate of 1 kg per cycle. It is assumed, that sulphuric acid is taken for stripping.

Krauss et al. (1999) reports for the “mixing and pumping of diluted leach, extracting agent and old electrolyte” in the copper-extraction an energy consumption of 350 kWh per t. Therefore this value has been taken as a proxy.

**Electrolysis (Reduction):** The resulting liquor after solvent extraction has an average gallium concentration of 145 g / litre. From this solvent, the gallium can be directly extracted via electrolysis. Since of missing data for electro winning, the related value for copper has been used: 2.22 kWh per kilogram of Gallium (Dresher 2001).

Meijer et al. (2003) assumed a material efficiency of 90% for electrolysis and purification (including partial reuse of waste), therefore an overall efficiency of 81% was assumed. However, the uncertainty is relatively high.

**Tab. 3.5 Key-figures of solvent extraction**

|                                | Unit        | Amount | Remark                                              |

| Average production per cycle   | kg Ga/Cycle | 1      | Assumption                                          |

**Tab. 3.6 Consumption of solvent and acid, Source: Selvi et al. (2004)**

|                                      |          |              | Re-use     | per kg Gallium |
|--------------------------------------|----------|--------------|------------|----------------|
| Total of solvent                     | 100 vol% | 8514 litre   | -          | -              |
| Kelex 100                            | 10 vol%  | (851 litre)  | 30-times   | 28.4 litre     |
| Versatic 10                          | 5 vol%   | (426) litre  | 3900 times | 0.11 litre     |
| n-decanol                            | 8 vol%   | (681) litre  | 3900 times | 0.17 litre     |
| Kerosene (as diluent)                | 77 vol%  | (6556) litre | 3900 times | 1.68 litre     |
| Acid: H <sub>2</sub> SO <sub>4</sub> | 100 vol% | (8514) litre | 3900 times | 2.18 litre     |

**Transports:** As the installations for gallium extraction are within the aluminium-plants, no transport of the Bayer liquor has been accounted for. Since it is assumed, that the production takes place in Europe, the transport of solvents and limestone is calculated with the standard distance from ecoinvent (see Tab. 3.7).

Tab. 3.7 Standard distances for transports of solvents and acid

| Type of transport | Distance                      | Source:                    |
|-------------------|-------------------------------|----------------------------|
| Railway           | 200 km in Europe (production) | Frischknecht et al. (2004) |
| Lorry             | 100 km in Europe (production) | Frischknecht et al. (2004) |

**Purification:** Meijer et al. (2003) describes the process of fractional crystallization for producing semiconductor grade gallium. The theoretical values for fractional crystallization are estimated with the energy needed for heating the metal from room temperature to melting-temperature and the heat of fusion. It is assumed that this process has an energy efficiency of 50%. No other purification methods have been taken into account.

Tab. 3.8 Physical properties of gallium to calculate the process of purification

|                        |                                                                                                                                                  |
|------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------|
| Heat of fusion per mol | 5,59 kJ/mol                                                                                                                                      |
| Heat of fusion per kg  | 80.2 kJ/kg                                                                                                                                       |
| Heat Capacity per mol  | 25.86 J·mol <sup>-1</sup> ·K <sup>-1</sup> (25°C)                                                                                                |
| Weight                 | 69.7 g/mol                                                                                                                                       |
| Heat Capacity per mol  | 371 J·kg <sup>-1</sup> ·K <sup>-1</sup> = 0.371 kJ·kg <sup>-1</sup> ·K <sup>-1</sup>                                                             |
| Melting point          | 29.7° C                                                                                                                                          |
| Room temperature       | 20° C                                                                                                                                            |
| Calculation            | $(9.7^{\circ}\text{C} \cdot 0.371\text{ kJ}\cdot\text{kg}^{-1}\cdot\text{K}^{-1} + 80.2\text{ kJ}\cdot\text{kg}^{-1}) / 0.5 = 0.0465\text{ kWh}$ |

**Infrastructure:** As there is no specific data about the gallium production available, proxy-data has been used: For the processes of enrichment and extraction, the infrastructure of “chemical plant, organics” is considered, the electrolysis takes place in the plant of “aluminium electrolysis”.

**Waste and Emissions:** No specific data is available. Richardson (2002) reports a typical loss of 0.05% of feedstock on refinery storages. Therefore a yearly loss of 0.05% \* 8520 l = 4.26 litre of organic solvent is emitted to the air. It is assumed, that 50% of this stream consists of NMVOC. The sulphuric acid is neutralized with calcium carbonate, each Mol of calcium carbonate neutralize 1 mol of sulphuric acid. The worst-case scenario represents the fact, that carbonate and sulphate are emitted as ions into the water. It is more likely, that they will be precipitated as salt.

It is assumed, that solvents as Kelex 100, Versatic 10, n-decanol or Kerosene, which have to be replaced, are sent to hazardous waste incineration.

### 3.6.3 Gallium, at regional storage

Since the production of gallium take place all around the world, the transport distance to regional storage has been estimated on the base of Kazakhstan (Russia and Kazakhstan produce 27% of worldwide gallium production) to Europe. Gallium is with an average price of 500US\$ per kilogram a precious metal, therefore the transport was considered with airplane over a distance of 4300km (Distance: Kazakhstan-Moskau-Germany)

Tab. 3.9 Standard distances for transports of solvents and acid

| Type of transport | Distance                               | Source:                                 |
|-------------------|----------------------------------------|-----------------------------------------|

| Airplane          | 4300km from Kazakhstan to Germany      | Estimation                              |

#### **3.6.4 Data Quality**

Data for the steps in the gallium production are roughly estimated. The values for the production and purification steps stem from older experimental sources. The proxy chosen to represent the electrolysis however is decreasing the overall quality.

|                    | GeneralComment             | This dataset is designed for accounting for resource depletion in the gallium production. As gallium is assumed to be a by-product of the aluminium production, no upstream burden is allocated to the gallium solved in the bayer liquor. Do not use this dataset for the production of gallium. | Production of gallium from Bayer-liquor, purification to 99.9999% (6N)                                                                        | Transport of gallium to european regional storage, this module calls the module "gallium, semiconductor-grade, at plant".    |

## 4 Cadmium purification and cadmium compounds

### Acknowledgement

We thank Vasilis Fthenakis for the information provided in a personal communication.

### 4.1 Introduction and Overview

In thin-film solar cells, cadmium compounds like cadmium telluride, cadmium sulphide or cadmium chloride are used for different tasks (photovoltaic junction, buffer-layer or back contact). For a more in-depth explanation about the use of cadmium compounds and the physical principles in a thin-film solar cell, see Karpov et al. (2005). Cadmium compounds are also used in other fields, mainly for electronic devices, detectors and pigments for painting.

Fig. 4.1 shows an overview of the inventoried cadmium compounds for solar industry, including the purification of cadmium as an intermediate step. All compounds are of high-purity (99.99 % to 99.9999 %), according to the requirements of the thin-film-solar cell manufacturers.

Fig. 4.1 Overview of the inventoried cadmium compounds

The cadmium compounds consist of the elementary materials of cadmium, tellurium, sulphur and chlor. Therefore no reserves or resources are mentioned here, estimations about the resources can be found in the corresponding chapters.

### 4.2 Characterisation of cadmium compounds

The appearance of cadmium compounds is in the range of dark black, grey-metallic up to yellow-orange, depending on the bounded element to the cadmium. All cadmium compounds are toxic.

## 4.3 Production and Use of cadmium compounds

### 4.3.1 Cadmium, semi-conductor grade

High purity cadmium metal is essential for the preparation of compound semiconductors such as CdTe, HgCdTe, CdZnTe, CdS or CdSe. These semiconductor devices are primarily used as solar cells, IR detectors, imaging devices, electro-optic modulators, fluorescence and thermoelectric coolers. The production of semiconductor compounds requires high-purified (6N and above) cadmium metal (Ali et al. 2004).

### 4.3.2 Cadmium telluride (CdTe)

CdTe is a basic component of solar cells and is used as a several micrometers thin coating (Guilinger (1999b)). Another application is the use of CdTe for optical infrared devices (alloyed with mercury) or a solid-state x-ray and gamma ray detector (alloyed with zinc).

Menezes (2001), Izumi (2004) and Fthenakis (2000) describe the recycling of CdTe from photovoltaic-waste. However, cadmium compounds are not recycled on an industrial-scale and are, therefore, not accounted for here.

Four companies in the United States, two in Europe and one in Japan produce CdTe currently. Their monthly output varies between 45 kg to 270 kg (Guilinger 1999b). The shape of the produced CdTe is either in form of fragments (<1.5mm) or powder (<0.5mm). The typical purity is 99.999% CdTe with some ppm-parts of Copper, Iron, Lead, Bismuth, Nickel and Silicon.

### 4.3.3 Cadmium chloride ( $\text{CdCl}_2$ )

Cadmium chloride is used as "Cadmium Yellow" (a brilliant yellow pigment) and for electroplating in the industry. In the production of thin-film-solar cells,  $\text{CdCl}_2$  is used as an auxiliary material for electroplating of the CdS-buffer-layer.

### 4.3.4 Cadmium sulphide ( $\text{CdS}$ )

CdS is used in thin film solar cells as a junction partner in CIS<sup>6</sup> and Cd/Te solar cells. The CdS layer itself is not intended to absorb light but instead allows light to pass through to either the CIS or CdTe substrate. Therefore, the CdS layer must be thin (30 to 100 nanometre) in order to allow sufficient light to pass through. A purity of minimal 99.99% (4N) is required.

CdS is also used as pigment, that is valued for its good thermal stability in many polymers, for example in engineering plastics. By adding selenium in its formula it is possible to obtain colours ranging from a greenish yellow to red violet. Pigments do not necessarily need a purity as high as for solar cells.

## 4.4 Life cycle inventories

### 4.4.1 Cadmium, semi-conductor grade

This section is mainly based on the report of Ali et al. (2004), additional information was taken from Fthenakis & Kim (2005); Fthenakis (2004). The high purity cadmium metal (99.9999% or 6N) can be produced either by zone refining process techniques or vacuum distillation. Although both techniques have their distinct purification profiles, vacuum distillation is more appropriate since the yield is higher in less time (Ali et al. 2004).

Vacuum distillation reduces the atmospheric pressure above the cadmium metal in order to decrease the boiling point. The following setting is described at laboratory-scale (Ali et al. 2004):

- The system consists of two cylindrical crucibles. The evaporator and the condenser are made with high-density graphite (150 mm OD x 120 mm ID x 300 mm Ht / 200 mm Ht). The two cylinders are enclosed in a reactor of stainless steel, its vacuum is  $2.1 \cdot 10^{-3}$  Torr.
- The condensation temperature in the inner wall of the collector is maintained at around 270°C, i.e. below cadmium freezing point.
- The cadmium metal in the evaporator is heated up to a temperature of 450°C.
- On average, it takes 5 hours for the entire deposition of 2 kg cadmium. Three stages of purification are necessary to obtain a purity of 99.9999%. The reported yield varies within 70% and 86%, with a geometrical mean of 77%.

**Purification of cadmium:** For an industrial production. A larger reactor is assumed for a continuous production. Due to the better ability of control, the energy source is electricity. Fthenakis<sup>7</sup> reports an energy consumption from 12'200 kJ/kg to 15'800 kJ/kg. For this project, the geometric mean of 13'880 kJ/kg was used.

Three stages of purification are necessary to obtain a purity of 99.9999%. Each stage has an average yield of 77%. The total yield is 46% for a purification setting of 3 cycles. The loss of 54% is captured

---

<sup>6</sup> CIS stands for Copper-Indium-Diselenid

<sup>7</sup> Personal communication of V. Fthenakis to N. Jungbluth, November 2006

in HEPA-Filters<sup>8</sup>, as described in Fthenakis (2004). The efficiency of HEPA filters in collecting particulates is reported with 99.97%, the rest is emitted to the air. It is assumed, that the filtrate can be used again for a new purification cycle.

**Infrastructure:** The infrastructure has been roughly assessed with the dataset of the organic chemical plant.

**Transports:** The transport has been calculated with the standard distances of ecoinvent (see Tab. 4.2).

Tab. 4.2 Standard distances for transports

| Typo of transport | Distance                   | Source:                    |
|-------------------|----------------------------|----------------------------|
| Railway           | 200 km in USA (production) | Frischknecht et al. (2004) |
| Lorry             | 100 km in USA (production) | Frischknecht et al. (2004) |

**Emissions and Waste:** As there are no other materials used in the processes, only the emissions of cadmium into the air has been taken into account:  $(1-99.97\%) * 2\% * 1 \text{ kg Cd} = 6 * 10^{-6} \text{ kg}$  per kilogram purified cadmium.

#### 4.4.2 Cadmium telluride, semi-conductor grade

Pinheiro (2006) reports different forms of CdTe used in close spaced sublimation (CSS)-techniques: single-crystal or polycrystalline wafers, powders, pellets or pieces, CdTe film deposited onto glass, molybdenum substrate (CdTe source-plate), sintered CdTe powder. Therefore, various techniques are used to produce CdTe in one or another form.

Guilinger (1999b) and Triboulet (2004) describes the crystal precipitation: High purity (5N to 6N) cadmium and tellurium are synthesized by melting the elements at a temperature of 1092°C in quartz tubing. The reaction is exothermic. The cadmium and tellurium must be of high purity because con-

<sup>8</sup> HEPA stand for *High Efficiency-Particulate Air*

taminates can cause an explosion. CdTe can only be produced in small batches of around 1.3 kg, because of the volatility of the chemical reaction.

Harman (1985) reports the preparation of CdTe for substrates: “Elements are sealed in evacuated, carbon-coated quartz tubes. The capsule is placed in a single furnace which is initially in a nearly horizontal position. A slight tilt in the furnace keeps the liquid and solid material at the small diameter end of the tube. The temperature of the furnace is raised to its final temperature of about 1110°C, at the conical tip end approximately 100°C lower. The temperature of the growth tube is held for about 16 to 20hrs, then the furnace is rotated about 90° to a vertical position. After the temperature is stabilized, the tube is lowered at a rate of about 1.2mm/hr until the solution has completely solidified.”

**Production and purification of cadmium telluride:** Since no production details about the use of resources are available, we assume the following production:

- Resources: The reaction is according “the stoichiometric quantities of high purity elements “ (Harman (1985)):  $1 \text{ Mol Te (} = 127.6 \text{ g)} + 1 \text{ Mol Cd (} 112.4\text{g)} \rightarrow 1 \text{ Mol CdTe (} 240 \text{ g)}$  According to Frischknecht et al. (2004), a yield of 95% was assumed.
- Energy: Fthenakis (see Footnote 7) report the needed energy for different processes and/or producers: Minimal 37'400 kJ/kg produced CdTe have to be used, the maximal value is 53'600 kJ/kg. In this project, the geometrical mean of 44'770 kJ/kg is used for an average production process. As the process needs a precise controlling, electricity is used as energy source.

**Infrastructure:** The infrastructure has been roughly assessed with the dataset of the organic chemical plant.

**Transports:** see Tab. 4.2 in Section 4.4.1

**Emission and Waste:** With a yield of 95% and the mentioned HEPA-filters, the emissions are:  $(1-99.97 \%) * 2 \% * 1 \text{ kg CdTe} = 6 * 10^{-6} \text{ kg of CdTe}$ . The emissions are accounted as “cadmium emission into air, high population density”.

#### 4.4.3 Cadmium chloride, semi-conductor grade

Cadmium chloride can be produced either by reaction of molten cadmium and chlorine gas at 600°C or by dissolving cadmium metal (or the oxide) in hydrochloric acid (Schulte-Schrepping & Piscator 2002). As data from literature is not available, the process and material consumption has been roughly estimated.

**Production of cadmium chloride:** Anhydrous cadmium chloride can be prepared by the action of anhydrous chlorine or hydrogen chloride gas on heated cadmium metal. The following reaction has been assumed:

or with an efficiency of 95% for synthesis, see Frischknecht et al. (2004):

As no further information about the energy consumption are available, an estimation based on the enthalpy has been made: The heat capacity of cadmium is  $26.02 \text{ J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$ , as the melting temperature of cadmium is about 320°C, we consider a difference of temperature of 300°C for heating the cadmium. The heat of fusion of cadmium is  $6'210 \text{ J}\cdot\text{mol}^{-1}$ , we estimate an overall efficiency of 50%.

Heat capacity:  $300 \text{ K} * 26.02 \text{ J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1} = 7.8 \text{ kJ}$

Heat of Fusion:  $6.2 \text{ kJ}$

Sum:  $14 \text{ kJ} = 0.014 \text{ MJ} = 0.0039 \text{ kWh} \rightarrow 0.0078 \text{ kWh/mol}$  (incl. efficiency of 50%)

As no information about purification is available, presumably the environmental impacts are underestimated.

**Infrastructure:** The infrastructure has been roughly assessed with the available dataset of the organic chemical plant.

**Transports:** see Tab. 3.7 in Section 4.4.1

**Emission and Waste:** From the molten cadmium, some emissions are considered. We assume the same efficiency of production process as for the purification of cadmium (see section 4.3.1) Therefore,

we assume that from 0.645 kg Cadmium 77% are converted into cadmium chloride, the rest is captured in HEPA-filters with an efficiency of 99.97%:  $(1-99.97\%) * 2\% * 0.645 \text{ kg Cd} = 3.876 * 10^{-6} \text{ kg}$  per kilogram cadmium chloride. The generated hydrogen is also emitted into the air.

#### 4.4.4 Cadmium sulphide, semi-conductor grade

This part is mainly based on the reports of Guilinger (1999a) and Faria & Chiola (1981). Guilinger (1999a) reported that in 1999 Asarco in the United States was the only producer of semi-conductor grade cadmium sulphide. It is assumed, that the production today also takes place in the US. Cadmium sulphide is being produced commercially by two methods:

- **Hydrometallurgical:**  
According to Guilinger (1999a), this aqueous technique of producing CdS involves a number of handling steps and is a complex procedure. According to Faria & Chiola (1981), is the normal procedure “dissolve a cadmium salt in water, preferably the chloride or sulphate, and then bubble hydrogen sulfide through the solution to precipitate essentially all of the cadmium in the form of cadmium sulfide.” The reported yield is quite high, anionic and cationic impurities co-precipitates with the cadmium sulfide. The following purification involves extensive washing and leaching, until a high purity of the output product can be reached.
- **Thermal:**  
This technique involves the fusing of cadmium and sulphide material. The production rate can be high, but size distribution and purity of the final product can be a problem. Therefore re-processing is necessary to achieve a consistent product. This process is generally used to produce lower grade CdS for use in pigments.  
According to Faria & Chiola (1981), the purification of thermal cadmium sulphide can be done with hydrogen sulfide: “luminescent grade cadmium sulphide is placed in a quartz tube reactor and a flow of nitrogen is maintained while the temperature is raised to about 500°C. Hydrogen sulfide is used to replace nitrogen and the temperature in the reactor is raised to about 1000°C. The temperature is held for 0.5h and then cooled down to 500°C under the hy-

drogen sulfide flow. The hydrogen sulfide is shut off and nitrogen is introduced while cooling the material to ambient temperature.”

**Production of cadmium sulphide:** Since no specific information about the production process is available, this part is mainly based on assumptions. It is assumed that the reaction is according to the stoichiometric quantities:  $1 \text{ Mol CdCl}_2 (= 183.3 \text{ g}) + 1 \text{ Mol H}_2\text{S} (34.1) \rightarrow 1 \text{ Mol CdS} (144.5 \text{ g}) + 1 \text{ Mol HCl} (112.4 \text{ g})$  According to Frischknecht et al. (2004), a yield of 95% was assumed. As no information about the energy consumption is available, the proxy-value of cadmium chloride (see section 4.4.3) is used instead (14 kJ per kg produced cadmium sulphide). As no information about a purification are available, presumably the environmental impacts are underestimated.

**Infrastructure:** The infrastructure has been roughly assessed with the available dataset of the organic chemical plant.

**Transports:** see Tab. 3.7 in Section 4.4.1

**Emission and Waste:** Guilinger (1999a) stated that “(The production) does generate a cadmium contaminated liquid waste stream that is environmentally difficult to handle and neutralize.” Therefore, a cadmium stream into the water is assumed. As a first estimation, the related value from zinc production has been chosen ( $2.60 \cdot 10^{-6}$  kg cadmium per kg cadmium sulphide). However, this value is fairly uncertain.

|                             | 492 GeneralComment             | This datasets describes the production of high-grade cadmium (99.9999%) from metallurgical cadmium. This purity of cadmium can be used in the production of various cadmium compounds. | This datasets describes the production of high-grade cadmium telluride (99.999%) from cadmium and tellurium. This purity of cadmium telluride can be used in the production of thin film solar cells. | This datasets describes the production of high-grade cadmium chloride (99.999%) from cadmium and hydrochloric acid. This purity of cadmium chloride can be used in the production of thin film solar cells. | This datasets describes the production of high-grade cadmium sulphide (99.99%) from cadmium and sulfuric acid. This purity of cadmium sulphide can be used in the production of thin film solar cells. |

## Part XI

# Tantalum Powder

Data v2.1 (2009)

Author: Mischa Classen, Empa Dübendorf

Review Roberto Dones, PSI

Classen M., Althaus H.-J., Blaser S., Tuchs Schmid M., Jungbluth N., Doka G., Faist Emmenegger M. and Scharnhorst W. (2009) Life Cycle Inventories of Metals. Final report ecoinvent data v2.1, No 10. EMPA Dübendorf, Swiss Centre for Life Cycle Inventories, Dübendorf, CH, Online-Version under: <http://www.ecoinvent.ch>.

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1

## Comments to version 2.1

This part and all data correspond to the part and data reported in version 2.0. No changes were made.

## Summary

The inventories of mining of tantalum containing ores and the production of capacitor grade tantalum powder are documented in this report. The inventory is based on the environmental reporting of the most important producer. The production of capacitor grade tantalum powder is based on theoretical models, similarity assumptions, and estimations. No recycling (secondary tantalum) is modelled. Hence, this dataset represents primary tantalum powder.

The production of tantalum metal, as it is used in the steel industry for alloying, follows a different process path. It includes the processing of  $K_7TaF_7$  with subsequent remelting in electron beam furnaces, which gives much higher burdens than the process described in this chapter. Therefore, the tantalum powder dataset described in this report is not recommended for use to represent tantalum metal manufacturing

# 1 Introduction

The main uses of Tantalum are in the alloying of high temperature steels and as metal powder in capacitors used in the microelectronic industry. Today the biggest share of Tantalum goes into the capacitors used in mobile applications such as mobile phones, handheld and laptops. Due to its easy processing and favourable electric properties it is widely used. Although the price for Tantalum has risen drastically, discussed alternatives – alumina or niobium based capacitors – are in their infancy. The price boom has led to a proliferation of small scale mining activities mainly in the Republic Congo during the Civil War in 1998 – 2004 that led to uncontrolled exploitation (Behrendt et al., 2007).

Since the production of capacitor grade Tantalum is extensive and the material itself is used in microelectronics in comparatively large amounts, it plays a key role in the environmental assessment.

## 2 Material Characterisation

Tantalum is dark, dense, ductile, very hard, easily fabricated, and highly conductive of heat and electricity. The metal is renowned for its resistance to corrosion by acids; in fact, at temperatures below 150 °C tantalum is almost completely inert to attack by the normally aggressive aqua regia. It can be dissolved with hydrofluoric acid or acidic solutions containing the fluoride ion and sulphur trioxide, as well as with a solution of potassium hydroxide. Tantalum's high melting point of 3017°C (boiling point 5458°C) is exceeded only by tungsten and rhenium (Wikipedia Contributors, 2006.).

## 3 Reserves and Production

Tantalum is 54th in order of abundance of the elements in the Earth's crust (2.1 g/t). In many deposits, it occurs in association with the much more abundant niobium (24 g/t). The most important tantalum-containing minerals are tantalite, wodginite, microlite (the tantalum-rich end member of the pyrochlore series), and columbite (Tab. 3.1).

In the past, most of commercial tantalum came as a by-product of tin smelting especially in Thailand. Since these deposits are now largely depleted (Forrest, 2004) the tin production in this area has been decreased and is today of minor importance for tantalum production. Therefore in future the tantalum from tin slag will be of reduced importance.

**Tab. 3.1** Composition of important tantalum-containing minerals (Andersson et al., 1996).

| Mineral        | Composition                                                          | Ta <sub>2</sub> O <sub>5</sub> content, % | Nb <sub>2</sub> O <sub>5</sub> content, % |
|----------------|----------------------------------------------------------------------|-------------------------------------------|-------------------------------------------|
| Tantalite      | (Fe, Mn)Ta <sub>2</sub> O <sub>6</sub>                               | 42 – 84                                   | 2 – 40                                    |
| Microlite      | (Na, Ca)(Ta, Nb) <sub>2</sub> O <sub>6</sub> F                       | 60 – 70                                   | 5 – 10                                    |
| Columbite      | (Fe, Mn)(Nb, Ta) <sub>2</sub> O <sub>6</sub>                         | 1 – 40                                    | 40 – 75                                   |
| Wodginite      | (Ta, Nb, Sn, Mn, Fe, Mn) <sub>16</sub> O <sub>32</sub>               | 45 – 56                                   | 3 – 15                                    |
| Yttrotantalite | (Y, U, Ca)(Ta, Fe <sup>3+</sup> ) <sub>2</sub> O <sub>6</sub>        | 14 – 27                                   | 41 – 56                                   |
| Fergusonite    | (RE <sup>3+</sup> )(Nb, Ta)O <sub>4</sub> *                          | 4 – 43                                    | 14 – 46                                   |
| Strueverite    | (Ti, Ta, Nb, Fe) <sub>2</sub> O <sub>4</sub>                         | 7 – 13                                    | 9 – 14                                    |
| Tapiolite      | (Fe, Mn)(Nb, Ta) <sub>2</sub> O <sub>6</sub>                         | 40 – 85                                   | 8 – 15                                    |
| Euxenite       | (Y, Ca, Ce, U, Th)(Nb, Ta, Ti) <sub>2</sub> O <sub>6</sub>           | 1 – 6                                     | 22 – 30                                   |
| Samarskite     | (Fe, Ca, U, Y, Ce) <sub>2</sub> (Nb, Ta) <sub>2</sub> O <sub>6</sub> | 15 – 30                                   | 40 – 55                                   |

\* RE = rare earth element.

### 3.1 Primary Resources

The principal raw material with the highest potential for extracting tantalum is found in the pegmatitic deposits in Australia. The typical Ta<sub>2</sub>O<sub>5</sub> concentration in processible pegmatitic deposits suitable to processing, is less than ca. 0.1%. The uranium- and thorium- containing minerals yttrotantalite, strueverite, euxenite, and samarskite are sometimes relatively high radioactive, which limits their workability (Andersson et al., 1996). Today ores with contents of 200 ppm (0.02%) of Ta<sub>2</sub>O<sub>5</sub> are workable by means of open pit and bulk hydrometallurgical technology (Gille et al., 2006).

### **3.1.1 Ores**

Tantalum is mainly gained from Pegmatite as Tantalite. The tantalum production rates from tin slags (25%) and from secondary resources (20%) imply a global share of primary production from Tantalite ores of 55%. The main producer of tantalum is the company Sons of Gwalia (SGW) that mines today 50% of the known primary Tantalite reserves (Polyakov & Polyakova, 2003). The company has been producing around 55-60% of the world's tantalum from two mines in Western Australia, and in 2003 this figure reached almost 70% (Forrest, 2004). The reserves at Greenbushes and Wodgina mines together amount to 49'000 t Ta<sub>2</sub>O<sub>5</sub> at 240 ppm and an additional 47'000 t at 162 ppm (Sons of Gwalia, 2003).

The USGS data shows the high dynamic of the mine production during the last ten years. Today the production of ores is estimated to amount 1'500 t and 1'900 tantalum (contained in various intermediates and commodities) for the years 2004 and 2005 respectively (USGS, 2006).

### **3.1.2 Tantalum containing slags**

An important potential tantalum reserve lies in the so called Southeast Asian Tin Belt, stretching from China to Indonesia through Thailand and Malaysia, and consists of cassiterite (SnO<sub>2</sub>) that contains some tantalum and niobium. During tin smelting, the tantalum and niobium become concentrated in the slag (Andersson et al., 1996). This slag can be processed directly for tantalum and niobium recovery. Roskill Information Services (Gille et al., 2006) estimated that 25% of the 2002 worldwide demand in tantalum was covered by the recovery of tin slags from the Southeast Asian Tin Belt. Since many of these operations are closing down due to depletion and accompanying decreased profits in the tin market, this source today is of minor importance.

## **3.2 Secondary Resources**

Due to the high price of tantalum, the market of secondary resources remains attractive. In 2002 Roskill Information Services (Gille et al., 2006) estimated that 20% of the tantalum originates from tantalum bearing scrap.

## **3.3 Production**

The Tantalum Niobium International Study Centre TIC used to keep track of the production and demand of worldwide tantalum market until 2001. Data gathered from various sources show the development in the last ten years (Tab. 3.2). The supply of primary tantalum is largely monopolised by two large producers: HC Stark/Bayer GP (Germany) and the Cabot Corp. (U.S.). These two companies account for 85% of the world production of tantalum powder, tantalum wire, and tantalum oxides (Polyakov & Polyakova (2003)).

### 3. Reserves and Production

**Tab. 3.2** Compilation of Production, supply and demand of tantalum. Data has been drawn from different sources indicated below.

| YEAR | Tantalum Supply,<br>Production from tantalite, slags & scrap | Tantalum Demand     | Mine production <sup>5</sup> | Reserve <sup>5</sup> | Reserve Base <sup>5</sup> | Reserve Reach <sup>6</sup> |

## 4 Use

The Brussels-based Tantalum Niobium International Study Centre (TIC) estimates that in 2003 50% of the tantalum went into powder for capacitors, 15% into metal for chemical plants in corrosion resistant alloys, 10% into temperature resistant superalloys, 10% into cutting tools as TaC and 15% into speciality applications (Forrest, 2004). Most probably the special applications correspond to a great extent to the application in the military sector as liner material and in anti-armour warheads (Muller, 1996). TIC estimated that tantalum demand in 2003 reached 1'900 tonnes  $Ta_2O_5$  and increases at a rate of 7 to 8% to 2'200 tonnes in 2005 (Forrest, 2004).

Fig. 4.1 Applications of tantalum in 2003 (Sons of Gwalia, 2006).

The major use for tantalum, as metal powder, is in the production of electronic components, mainly capacitors and some high-end audio-grade resistors. Tantalum electrolytic capacitors exploit the characteristic of tantalum to form a protective oxide surface layer, using tantalum foil as one plate of the capacitor, the oxide as the dielectric, and an electrolytic solution as the other plate (Wikipedia Contributors, 2006).

Today, the tantalum electrolytic capacitor industry requires approximately 68 percent of the world's tantalum production. Tantalum capacitors are characterized by a very high volumetric efficiency of capacitance and very high reliability under extreme conditions. Compared with aluminum or ceramic capacitors, tantalum capacitors show a distinctly lower temperature and frequency dependence of their electrical properties. The typical application area of application of tantalum capacitors is shown in Fig. 4.2 (H.C. Starck, 2006).

Beside electronics, tantalum is used as alloying element in metals and superalloys as well as carbide for hard metals (Fig. 5.1). However, these applications are not covered by this dataset and are not discussed further.

Fig. 4.2 Application of tantalum in capacitors (H.C. Starck, 2006).

## 5 System Characterisation

Depending on the intended product and company, a multitude of processes are applied to extract the tantalum and to manufacture products from it. Different technologies exist to produce metallic tantalum products:

- From its **heptafluoride** by means of Electrochemic reduction (KF/KCl,) or metallothermic reduction with potassium (Yoon et al., 2005).
- From its **pentoxide** by means of a reduction with gaseous magnesium.

Both processes are to be found in the schematic in Fig. 4. As feedstock, slag from tin production is used apart from ores. Low grade tin slags are either enriched with scrap to form synthetic ores that can be subjected to the liquid-liquid extraction with MIBK (methyl isobutyl ketone, 4-methyl pentan-2-one) or else pass, together with tantalum containing scrap from electronic scrap, the calcination route. Secondary tantalum raw materials are always extracted by hydrometallurgical processes via tantalum pentachloride or oxide (Fig. 5.1).

Fig. 5.1 General overview of the production of tantalum products from different feeds (Andersson et al., 1996) and selection for the inventoried system (red).

Tantalum powders or semi finished products such as wires and sheets for applications in alloys and steel industry are mainly processed by the reduction of K<sub>2</sub>TaF<sub>7</sub> with sodium. The powder obtained is then pressed to bars, that are formed to ingots by electron beam melting and shaped to the desired form. This process therefore differs much from the capacitor powder production. Further information on the respective process is given in Albrecht & Ingalls (1983) and is not further discussed here.

In this report no overview of all processes can be given, but only the technologies relevant to the production of capacitor grade tantalum powder is regarded. Three different processes are applied in capacitor grade tantalum powder production (H.C. Starck, 2006), namely:

- Electron beam melted process (via  $K_2TaF_7$ )
- Na-reduced process (via  $K_2TaF_7$ )
- Mg-reduced process (via  $Ta_2O_5$ )

For capacitor powders, e.g. from H.C. Starck, all these three different processes are applied in dependence of the desired application. To cover the needs for higher volumetric capacitance and lower rated voltage, the magnesium reduced process is employed (Fig. 5.2). Since the miniaturisation of capacitors that are used in microelectronics require ever higher specific electric capacitance, the magnesium reduced process via the tantalum oxide is considered relevant in the context of this inventory.

Fig. 5.2 Tantalum powder production processes according to the application fields (H.C. Starck, 2006).

### 5.1.1 Production of Tantalum powder in ecoinvent

This inventory describes the production of tantalum powder for the use in capacitors in electric applications. The tantalum powder is produced from virgin tantalite ore to tantalumpentoxide which is reduced with magnesium vapour to tantalum powder. No secondary production from consumer scrap and also no by-product tantalum from tin production is considered. This dataset is exclusively meant to be used in the context of electronic devices, since the production of tantalum for alloying purposes follows a different route (Fig. 5.1).

The metadata of the established inventory is given in (Tab. 5.1), their exchanges are shown in (Fig. 5.4). The unit process data for the individual steps are presented in separate data for tantalite mining (Tab. 5.3), extraction (Tab. 5.5) and reduction (Tab. 5.7).

Tab. 5.1 Ecoinvent meta information for the processes for the production of 1 kg tantalum powder for capacitors.

| General Comment              | This dataset is functional for the use of tantalum as powder in capacitors of portable electronic devices. It is not valid for the use as an alloying element in steel. Only primary production from tantalite / pegmatite ore is considered. Tantalum as by-product from tin production is not considered.                                                                                                                              |
| Start Date                   | 2000                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| End Date                     | 2003                                                                                                                                                                                                                                                                                                                                                                                                                                     |

### 5.1.2 Mining of Tantalumpentoxide

Most of the tantalum is mined in the two operations Greenbushes and Wodgina in Western Australia. The resulting concentrates contain around 40% Ta<sub>2</sub>O<sub>5</sub>. An estimated worldwide 10% of Niobium supply originates from joint extraction with tantalite deposits (Polyakov & Polyakova (2003)). However, this coupled product is not modelled within this dataset.

The overall recovery of tantalum from ore ranges between 72-74% (73% is assumed in this study), upgrading (concentrating) the ore from 0.1% to 38% Ta<sub>2</sub>O<sub>5</sub> (Burt, 1996). Assuming an average ore concentration of 194 ppm (weighted mean of Greensbushes and Wodgina deposits, see Section 3.1 Primary Resources) 7067 t ore is required to produce 2.63 t concentrate containing 1 t Ta<sub>2</sub>O<sub>5</sub>.

The tantalite is currently mined in open pits – one underground pit in Greenbushes is suspended but may resume operation in the future. The dust emissions are approximated in both amount and particle

distribution approximated with specific values from copper mining from the CEPMEIP-Database<sup>1</sup>. The infrastructure has been approximated with the respective dataset for a generic non ferrous metal mine with 20'000 Mt ore throughput in 50 year lifetime. The use of conveyor belts has been assumed to be of the same specific value per tonne ore mined as in the copper production as approximation (see Tab. 5.2). Land use and occupation has been taken from Sons of Gwalia (2003). The remaining mass after separating the tantalite is the tailings that must be disposed of. The transport services reflect the transportation of tantalum oxide to the harbour by train (60 km) and further by ship to Germany (14'000 km) and train inland to the manufacturer (400 km).

### 5.1.3 Production of Ta<sub>2</sub>O<sub>5</sub>

As explained in the introduction of 5 *System Characterisation*, the adequate process for reducing the tantalite is assumed to make use of magnesium (see Fig. 5.2). HC Stark/Bayer patented a process with gaseous magnesium (Shekhter et al., 2001) is taken here as the method to produce tantalum powder. The process considered for the production of capacitor grade tantalum powder consists of the following steps (Gille et al., 2006, Fig. 5.3).

- Breakdown with HF
- Extraction with MIBK
- Selective extraction of Niobium
- Stripping of tantalum from MIBK
- Precipitation of oxide hydrates
- Calcination to Ta<sub>2</sub>O<sub>5</sub>
- Reduction of Ta<sub>2</sub>O<sub>5</sub> with magnesium vapour

Fig. 5.3 Hydrometallurgical Processing of Niobium and Tantalum (Eckert et al., 2001)

The ore concentrate, up to 40% Ta<sub>2</sub>O<sub>5</sub> (in this study 38%, see 5.1.2 *Mining of Tantalumpentoxide*), is dissolved in concentrated hydrofluoric acid (Andersson et al., 1996). Petrova et al. (1997) report extraction efficiency for artificial tantalum concentrate (including TaC bearing scrap) of 80-85% in traditional industries in 1996 and 95% with optimised parameters.

Gupta (2003) gives a stoichiometry in the leaching process of 16 moles of HF per 2 moles H<sub>2</sub>TaO<sub>6</sub> in solution. Eckert (1996) indicates large amounts of HF (2 t), H<sub>2</sub>SO<sub>4</sub> (3 t) and NH<sub>3</sub> (700 kg) required in 1990 to produce one tonne pure Ta<sub>2</sub>O<sub>5</sub>. Although the process advanced since then regarding regenerating the acids, no quantitative indication on the specific net requirements of the process chemicals can be made. In this study therefore the values of Eckert (1996) (also cited in Polyakov & Polyakova, 2003) are used.

The following reaction was assumed for subsequent calcination (dehydration):

This results in a theoretical energy requirement of 0.23 MJ heat per kg oxide, assuming an efficiency of 80%. The electricity demand for pumping was disregarded, because no information on this was available. Ammonia recovery is assumed to amount to 99.9% of the used ammonia in a 28% NH<sub>3</sub> solution (Eckert, 1996), the rest being emitted into the air. Also the spent HF is recovered as diluted solution. No process information for recovery of the spent reactants is available. Both recovered solutions are therefore regarded here to be by-products and leave the system burden free without substitution for process chemical inputs.

### 5.1.4 Reduction to Tantalum powder

Only little details are known from this reductive step, therefore the reasoning is based on the respective patent. The reduction is effectuated by means of magnesium vapour that is brought into contact with  $\text{Ta}_2\text{O}_5$  powder in a continuous process, e.g. in a rotary kiln or a multiple hearth furnace. The heat required is assumed to be supplied by electricity. The resulting product contains impurities in the order of 0.2% to 0.25%, most of it being oxygen (Andersson et al., 1996). In the calculation for this inventory therefore a process efficiency of 100% was assumed. An overview of the specific values and assumptions used is given in Tab. 5.6.

The energy required is calculated upon the reaction stoichiometry:

Normalised to 1 kg Ta output an amount of 1.22 kg  $\text{Ta}_2\text{O}_5$  and 0.336 kg Mg is needed as input materials. Assuming that Magnesium is added 10% in excess (Shekhter et al. (2001)), 0.369 kg Magnesium required is calculated ( $= 0.336 \text{ kg} * 110\%$ ). The unreacted magnesium is supposed to be recovered. Hence no burdens are allocated to it.

The reducing agent magnesium passes two phase transitions from solid state to liquid (8.95 kJ / mol) and from liquid to gas (127.6 kJ / mol). The total theoretical energy requirement therefore amounts to 136.5 kJ / mol with a stoichiometry of 13.81 moles Mg per kg Ta.

The magnesium oxide is removed from the tantalum powder with diluted sulphuric acid and cleaned with ultra pure water. Since no quantitative information on this last cleaning step is available, 3 kg of sulphuric acid and 2 kg of ultra pure water per kg Ta product were assumed. Furthermore it is assumed that the resulting magnesium sulphate in solution can be processed further. Considered as by-product it leaves the system burden free without substituting raw materials.

**Tab. 5.6** Specific values and assumptions used for calculation in the reduction step.

### 5.1.5 Transport and Infrastructure

The concentrate is assumed to be transported by train to the nearest port (60 km), by ship to Germany (14'000 km), then by train to the facility (400 km). Based on the ecoinvent quality-guidelines, developed for Europe, the chemicals are assumed to be transported 600 km by train and 100 km by lorry also in this case. An overview over the resulting transport service is given in Tab. 5.8. In this study, the infrastructure for extraction and reduction of tantalum pentoxide is estimated based on the module "chemical plant, organics", that has a built area of about 4.2 ha and an average output of 50'000 t/a (Althaus et al., 2003).

**Tab. 5.8** Inventory and calculations for transport and infrastructure.

## 6 Data Quality Considerations

The production process is rather new and not much is known from public sources about quantitative process measures. Therefore the data has been established based on reasoning and rough assumptions. Direct emissions others than dust and ammonia have been omitted due to lack of data. This might restrain the quality of this inventory, if omitted emissions prove to be important in the overall assessment. However, no estimation of the relative importance of this omission can be performed on the basis of the current information. Infrastructure requirement has been approximated with the related technology of copper mining and chemical plants. The uncertainty has been calculated with the pedigree approach. The data describe the production process supplying the demands for the use in capacitors for electronic devices. This dataset should not be used when tantalum is a substantial part of the system modelled (e.g. comparing different capacitor materials). It has to be stressed that this dataset is solely valid for tantalum powder that is used in capacitors. For all other uses of tantalum – namely: tantalum based superalloys in high temperature machinery and tantalum carbides in hard metals – this dataset is not applicable.

## Part XI

# Tin

Data v2.1 (2009)

Author: Hans-Jörg Althaus, EMPA Dübendorf

Review: Mischa Classen, EMPA Dübendorf

Update: Mischa Classen, Empa Dübendorf

Classen M., Althaus H.-J., Blaser S., Tuchs Schmid M., Jungbluth N., Doka G., Faist Emmenegger M. and Scharnhorst W. (2009) Life Cycle Inventories of Metals. Final report ecoinvent data v2.1, No 10. EMPA Dübendorf, Swiss Centre for Life Cycle Inventories, Dübendorf, CH, Online-Version under: <http://www.ecoinvent.ch>.

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1

## Comments on version 2.1

This part and all data correspond to the part and data reported in version 2.0. No changes were made.

## Summary

The production of tin is inventoried in the modules described in this report. Data reported are mainly based on theoretical models, similarity assumptions and estimations. Secondary sources of tin (recycling) is not considered, thus the overall data quality is poor.

Within ecoinvent, these data are used for representation of materials of minor importance. If in an LCA study one of these materials is of importance, the data should not be used.

This part is the excerpt from “Part VIII Other metals” in Althaus et al. (2004) that has been reorganised for the actual version 2.0. No changes from the original dataset v 1.1 are reported, hence no adjustments have been accomplished for the update to version 2.0. Note that the flow names in the tables displaying unit processes have not been updated to reflect the name changes with version 2.0.

# 1 Introduction

The information available for these inventories was rather sparse. Thus the data quality must be described as poor. One important shortcoming is the neglecting of tin recycling. Within ecoinvent, these data are used for representation of materials of minor importance. If in an LCA study one of these materials is of importance, the data should not be used.

## 2 Reserves and Resources Tin

The most important tin ore is cassiterite ( $\text{SnO}_2$ ), although small amounts of tin are recovered from sulphide minerals such as stannite ( $\text{Cu}_2\text{FeSnS}_4$ ). Although most tin is obtained from mining tin ores, cassiterite is also found in association with ores of tungsten, tantalum and lead and minor quantities of tin are recovered as by-products of mining these metals.

Tin occurs in both primary (typically acid igneous intrusive rocks) and secondary deposits such as alluvial and eluvial deposits. Only about 20 percent of the world's tin deposits occur as primary hard-rock veins or lodes. These ores contain predominantly high temperature minerals and commonly occur in close association with silicic granites. About 80 % of the world's tin deposits occur not as primary lodes, but as unconsolidated secondary or placer deposits in river beds and valleys or on the sea ground. The largest concentration of both onshore and offshore placers is in the extensive tin belt of South-East Asia, stretching from China in the north, through Thailand, Burma and Malaysia, to the islands of Indonesia in the south.

Compared to commercially viable deposits of copper, lead, zinc, nickel and bauxite, tin deposits are generally small. Further, tin is almost always found closely allied to the granite from which it originates.<sup>1</sup>

The tin production given in Tab. 2.1 is taken from the itri homepage<sup>2</sup> that refers to the bi-monthly 'Tin Monitor' published by CRU International Ltd.

Note: China and Russia are major tin producers but production data is not currently verifiable.

Tin is also gained from recycling. On one hand there is the recycling of "new scrap" that can be done easily. On the other hand there is the recovery of tin from tinplate which is becoming increasingly difficult, as the change to electrolytic methods of tinning is leading to very thin coatings which sometimes diffuse into the steel sheet. The recycling of this material will continue to be a technically and economically difficult task. In principle, two processes are used today for recovering tin from tinplate: the alkaline electrolytic method and the alkaline chemical method. Processing tin-containing alloys is easier than recovering tin from scrap tinplate. However, the tin content of many alloys has decreased over recent years, and cheaper materials have in some cases replaced alloys. Both these developments have tended to limit the potential for recovering secondary tin, and also explain why the amount of recovered tin in Europe has decreased from 15 800 t in 1980 to 13 300 t in 1990. (Graf (1997))

### 3 Characterisation of Tin

This information is based on Graf (1997).

Tin (Sn) exists in two crystalline modifications, the  $\alpha$ - and  $\beta$ -forms.  $\alpha$ -tin is also called grey tin while  $\beta$ -tin is referred to as white tin. Some physical properties of  $\alpha$ - and  $\beta$ -tin are listed in Tab. 3.1.

In the periodic table, tin lies on the boundary between metals and non-metals. The transformation of the  $\alpha$ - to the  $\beta$ -modification is accompanied by a complete change of lattice structure, affecting the physical, chemical, and mechanical properties. The transformation of  $\beta$ -tin (white tin) into  $\alpha$ -tin (grey tin) is of practical importance, as it involves a volume increase of 21 %. The transformation process requires a high energy of activation, and can be very strongly hindered. White  $\beta$ -tin can therefore exist for many years at  $-30\text{ }^{\circ}\text{C}$ . The presence of  $\alpha$ -tin seed crystals is important for the transformation process, and these are formed by repeated phase transitions. Foreign "elements" also affect the transformation temperature and rate. These can consist of impurities and deformations. Tin vapour consists of  $\text{Sn}_2$  molecules.

**Tab. 3.1 Physical properties of  $\alpha$ - and  $\beta$ -tin (Graf (1997))**

Tin is stable in dry air, but is considerably more rapidly oxidised at a relative humidity of 80 %. Bright metallic tin becomes dull within 100 d even in indoor atmospheres. Oxygen is rapidly and irreversibly chemisorbed, and the oxide layer formed grows at an exponentially increasing rate. Typical impurities present after metallurgical production (e.g., Sb, Tl, Bi, and Fe) promote oxidation. Treatment with carbonate or chromate solutions leads to passivation. For the use of tin in food packaging it is important that lactic, malic, citric, tartaric, and acetic acids do not react at all at normal temperatures or do so to a negligible extent, especially in the absence of atmospheric oxygen. This is also true for alcohols and hydrocarbons.

## 4 Use / Application of Tin

Important applications for Tin are:<sup>3</sup>

- Food packaging and culinary uses: Tinplate (sheet steel coated with a thin layer of tin) is the primary material for food canning and shares the beverage can market with aluminium.
- Electronics: The principal use of tin in electronics is in the use of solders for the joining of electronic components. But there are many other varied uses in the general electronics field.
- Tin chemicals: The biggest single use of tin chemicals is as PVC stabilisers, but besides this they are used in a very wide range of applications, for example as polymerisation catalysts in silicone resins and polyurethane foam manufacture, and in ceramic pigments.
- Plumbing solders: Plumbing solders containing lead are being replaced by safe tin-silver (usually 96.5 percent tin/3.5 percent silver) or tin-copper (97 to 99 percent tin/1 to 3 percent copper) alloys, particularly for drinking water systems.
- Engineering alloys: Tin is used as an alloy with other metals.
- Pewter and bronze: Pewter (an alloy containing about 92 percent tin with small amounts of other metals added for strength) has long been known for its decorative appearance and ease of working as a craft metal. Tin bronzes (alloys of copper with 5-20% tin) are renowned for their use in art castings and as bell metals.
- Dental amalgams: Dental amalgam contains about 13 percent tin by weight together with silver and mercury.
- Anti-corrosion and engineering coatings: Tin and tin-alloy coatings are widely used in the manufacture of bearings and in many kinds of machinery and fabricated parts, both for their anti-corrosion and lubricant properties.
- Wine capsules: A tin coating acted as a barrier layer in traditional lead-based capsules to prevent contact between the lead and the wine. Tin-lead capsules are now being replaced with other materials but the most prestigious and closest in feel to the traditional capsules, are made from almost pure tin.

Consumption of tin in the western world is around 200'000 tonnes per year. The dominant consumers are Europe (33%), USA (17%) and Japan (12%). The distribution of tin consumption is unusually weighted toward Europe where 46% of all beverage containers are tinplate in contrast to the USA where tinplate is not used for beverage containers. Consumption can be divided into four segments, tinplate (30%), solder (29%), alloys and coatings (25%) and chemicals (16%).<sup>4</sup>

## 5 System Characterisation

This chapter is mainly based on Graf (1997).

### 5.1 Overview

Tin is mined, beneficiated, smelted and refined. Fig. 5.1 gives an overview of the processes.

Fig. 5.1 Overview of tin production

### 5.2 Mining and beneficiation

No precise information is found on the amount of tin ore mined in the different types of mines. Based on descriptive information<sup>5</sup> it is therefore assumed that 20% of the tin ore is gained from underground mines and 40% each from open pit mines and from offshore deposits.

#### 5.2.1 Underground mining

Drilling and blasting is only needed in underground mining where depths can reach 1000 meters. Common technology for non-ferrous metal mining is applied. Tin ores are separated from the gangue using sorting methods based on density. The large variation in achievable tin concentration of about 6% to 60% in the ore is due to different sizes and intergrowth of the cassiterite with other minerals.

<sup>5</sup> <http://www.tintechnology.com/library/detail/library/Tin%20Mining.htm>, access date 14.03.03 and <http://www.murchisonunited.com.au/operations/renison.asp#production>, access date 28.03.03

Recoveries of around 75% of the tin are achieved by this beneficiation. Unacceptably high losses of material would occur if ore concentrates with higher tin contents were produced. Therefore, a pyrometallurgical "thermal ore beneficiation" stage is necessary prior to the actual reduction process. This is a volatilisation process that exploits the fact that the iron compounds and other slag formers have low vapour pressures at 1000 – 1500 °C, while SnO and especially SnS volatilise very readily. This technique can also be used to treat tin-containing slags. In the process where tin ore or slag is heated together with pyrite (FeS<sub>2</sub>) the SnO reacts to SnS and the FeS<sub>2</sub> to FeO. With careful process control, 90 – 95 % of the tin can be recovered as an oxidised product containing 40 – 60 % Sn.

Although this is at the lower end of the commercial viability we assume an average tin content of 0.1% in the crude ore that is mined underground and an average recovery of the tin minerals of 70%. Thus 1.43 tons of material has to be mined to gain 1 kg of tin from underground mines. With the assumed average density of 1.5 tons/m<sup>3</sup> crude ore this corresponds to 0.95 m<sup>3</sup> crude ore.

For a lack of specific information the energy consumption and the amount of explosives used for mining are calculated based on the values derived for platinum group metal (PGM) mining. The assumption underlying the calculation is that the respective consumption is proportional to the mass of crude ore extracted. The electricity needed for mechanical beneficiation is taken from Richter et al. (1996) and the water consumption is estimated. The in- and outputs for the thermal beneficiation step given in Tab. 5.2 are calculated with the values given in Tab. 5.1.

**Tab. 5.1 Values used for calculation of in- and output flows of the thermal beneficiation step.**

| SO <sub>2</sub> emissions to air [kg]                               | 0.9715                  | calculation based on assumptions         |

### 5.2.2 Open pit mining

For open pit mining it is assumed that no cap of the deposit exists. Water cannons operating at pressures of up to 1.5 MPa are used to separate the ore from the overburden. The mixture of water and heavy sand with about 70% tin content is then fed to the treatment plant.

The tin content in placer deposits lies in the range of 0.01 to 3%. We assume an average tin content of 0.1% in the crude ore that is mined and an average recovery of the tin minerals of 90%. Thus 1.11 tons of material has to be mined to gain 1 kg of tin from open pit mines. With the assumed average density of 1.5 tons/m<sup>3</sup> crude ore this corresponds to 0.74 m<sup>3</sup> crude ore. The thickness of the recoverable open deposit is assumed to be 5 meters. Thus 0.148 m<sup>2</sup> of land is transformed to mining area per kg of tin recovered. It is assumed that a mining site is depleted within 10 years and left for natural recultivation afterwards.

For a lack of specific information the energy consumption used for mining, the infrastructure needed therefore and the dust emissions generated by it are calculated based on the average values derived for iron ore and bauxite mining. The assumption underlying the calculation is that the respective consumption is proportional to the mass of crude ore extracted. No explosives are assumed to be used. The water consumption is estimated.

### 5.2.3 Offshore mining

Marine deposits are mined several kilometres offshore in depths of around 50 meters below sea level using bucket line dredges. Thus a similar mixture of water and heavy sand as in the open pit mining with water jets is won.

The tin content in placer deposits lies in the range of 0.01 to 3%. We assume an average tin content of 0.1% in the crude ore that is mined and an average recovery of the tin minerals of 90%. Thus 1.11 tons of material has to be mined to gain 1 kg of tin from offshore deposits. With the assumed average density of 1.5 tons/m<sup>3</sup> crude ore this corresponds to 0.74 m<sup>3</sup> crude ore. The thickness of the recoverable offshore deposit is assumed to be 5 meters. Thus 0.148 m<sup>2</sup> of benthos is transformed to mining area per kg of tin recovered. It is assumed that a mining site is depleted within 10 years and left for natural recultivation afterwards.

For a lack of specific information the energy consumption of open pit mining of tin ore is used assuming that the electricity used in open pit mining is replaced by diesel, burned in building machines with 5 times lower efficiency.

### 5.3 Production of crude tin

The beneficiated ores with the average tin content of 68% (20% with 50% Sn from underground mining, 80% with 70% Sn from open pit and offshore mining) are heated together with powdered coal in a reverbaratory furnace at 1200 °C. Thus a tin containing slag is formed. By a second melting in a sloping hearth the metallic tin runs off (97% purity) and a slag with about 8% Sn content is formed. This slag is recycled to the beneficiation step.

According to Richter et al. (1996), 15% to 20% carbon is added to the ore for smelting and 75 to 100 kg heating oil per tonne of ore is burned for heating. About 10-14% of the input ore mass is turned to slag that is used in a secondary smelting. This process uses 550 to 1000 kWh electricity (in an electric furnace) and 1 to 10 kg of electrodes per ton of slag. Beside that, 122 kg coal, 67 kg of gypsum and 39 kg of limestone are needed per ton of slag. 136 kg of secondary slag has to be landfilled per ton of primary slag input. These values are used to calculate the in- and outputs of the smelting of tin (see Tab. 5.3).

**Tab. 5.3 In- and outputs for smelting per kg pure tin (based on Richter et al. (1996))**

|                                                  |                          |                                     |                                    |                                     |

1 calculated from value per input, tin fraction in slag, fraction of ore input to slag and fraction of extraction from slag

2 calculated from input per kg slag and slag to smelting per kg ore input

3 calculated from input per kg slag and slag to smelting per kg Sn input

4 calculated from input per kg slag and slag to smelting per kg Sn output

5 value given in Richter et al. (1996)

### 5.4 Refining

The crude tin obtained by the reduction process is insufficiently pure for most applications. Refining can be done pyrometallurgically or by electro-refining.

Electro-refining can only be operated at low current densities, leading to low process rates and inefficient utilisation of energy. Thus electro-refining is only worthwhile if the tin contains high concentrations of noble metals. It is therefore not considered in this study.

There are different types of pyrometallurgical refining depending on the impurities that have to be removed. All the processes have in common that liquid tin is treated in a way that the impurities form intermetallic compounds that can be removed. For removing arsenic it is even necessary to have a vacuum over the liquid metal. Graf (1997) gives an energy demand of 400 to 700 kWh per ton tin for heating and providing the vacuum. The average of this value is used as electricity input for lack of other information.

## **5.5 Emissions**

### **5.5.1 Air**

Beside the emissions from heat generation there are dust emissions from mining, SO<sub>2</sub> emissions from beneficiation and CO<sub>2</sub> emissions from the reduction of SnO with carbon.

### **5.5.2 Water**

No information about emissions to water is available. The beneficiation process being predominantly mechanical is not believed to be a relevant source of water emissions. Some emissions are likely to occur from waste gas treatment in the thermal beneficiation of the ore from underground mining.

## **5.6 Waste**

The overburden of mining is refilled in the mine and not treated as waste. Acid rock drainage (ARD) that is possibly occurring where sulfidic ores are present is thus not modelled for this waste fraction. The only waste considered as such is the secondary slag that is landfilled. No detailed information about the composition of this slag was found. From the composition of the crude ore it is assumed that the slag contains mainly Sn, SiO<sub>2</sub>, Fe, Ta<sub>2</sub>O<sub>5</sub>, TiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, CaO, Nb<sub>2</sub>O<sub>5</sub> and As.

For a lack of better data the disposal of slag from unalloyed steel making in the electric arc furnace (EAF) is inventoried as a proxy.

## **5.7 Tin production inecoinvent**

The background information to the process "tin, at regional storage" are given in Tab. 5.4, flows are shown in Fig. 5.2.

## **5.8 Data quality**

Data uncertainty is derived using the Pedigree matrix as described in (Frischknecht et al. (2003)).

Most data for the tin production are assumptions based on qualitative information and theoretical models. Thus uncertainty is rather high. These data are of insufficient quality for LCA where tin or tin derived products (e.g. solders) play an important role.

Tab. 5.4 Meta information for the tin production processes

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1

## Comments on version 2.1

This part and all data correspond to the part and data reported in version 2.0. No changes were made.

## Acknowledgement

The authors thank Johanna Öster-Haagensen and Liv Kari Sivertsen from the research centre of Norsk Hydro in Porsgrunn, Norway for her support while interpreting and using the environmental data provided by Norsk Hydro.

## Comments on this part

This part corresponds to the original part “Other Metals” in Althaus et al. (2004) that described the metals lead, zinc and magnesium and has been suspended for this version 2.0. The original content has been distributed over the new part VII on lead, zinc, cadmium and indium as well as this part that now exclusively is designated to the description of magnesium and its alloys AZ91 and AlMg3. Chapter “Cumulative Results and Interpretation” of the original report has been deleted for the current update.

## Summary

Magnesium, metal alloys containing magnesium, i.e. AZ91, AlMg3, and die castings are important construction materials, e.g. in the automobile sector or for electric equipment. The environmental impacts of magnesium production are investigated as a unit process over the life cycle from raw material extraction until the gate of the factory. The investigation is based on environmental data provided by a producer and on a literature research. High uncertainties still exist for the average energy and SF<sub>6</sub> use in magnesium industry.

## Keywords

AlMg3, Aluminium alloys, AZ91, Magnesium, Magnesium alloys, Magnesium die casting

# 1 Introduction

The metal magnesium is getting more and more important as a construction material for different technical purposes. It is used as a lightweight material and as an addition to metal alloys such as MgAl3. This inventory for magnesium and related materials is meant to be used as a background unit process for the life cycle assessments of technical products such as e.g. equipment for electricity transmission or photovoltaic systems.

## 2 Reserves and Resources of Materials

Magnesium can be extracted from seawater, from minerals (dolomite, magnesite and brucite) or can be gained by recycling materials. It is the eighth most abundant element in the earth's crust. Seawater contains about 0.13wt% Magnesium (Hoy-Petersen et al. (1999)).

Norsk Hydro uses about 207 000 tonnes of dolomite with an approximate magnesium content of 26 330 tonnes and seawater to produce 106 000t of magnesium (Hydro Magnesium (1999b)).

## 3 Characterisation of the materials

Magnesium is a silvery white, light metal. It burns in air with an intense white flame. Pure magnesium has a high resistance to corrosion because its galvanic activity is low (Hoy-Petersen et al. (1999)).

## 4 Production and Use of Magnesium

The most important producer in Europe is Norsk Hydro with an annual production of 105'600 tonnes in 1998 while the total annual production was about 372'000 tonnes. Tab. 4.1 shows an overview of the production places of magnesium. It is important to know that the import of magnesium from the eastern world plays an important role for meeting the western worlds demand. But there are not many shipments between Europe and America. Various investment projects are going on to increase the production capacities due to the increasing demand. Due to the possibility to produce magnesium from seawater there is no shortcoming of resources for production.

Tab. 4.1 Magnesium production and consumption in 1996-97 (Aroule (1998))

| Countries and companies            | Production | Type of production process                              | Im-/ Exports |

| China (200 producers)              | 80         |                                                         |              |
| <b>Total</b>                       | <b>372</b> | 80% electrolytic, 20% thermal                           |              |

Magnesium is used for different technical purposes. The consumption of magnesium in the western world is summarized in Fig. 4.1 (Avedesian & Baker (1999)). Aluminium alloys and production of die-castings are the main purposes for consumption.

Fig. 4.1 Consumption of magnesium in Western world in 1997 (total 333'700 tonnes). Amount used for magnesium alloys (die castings) is shown shaded (Avedesian & Baker (1999)).

## 5 System Characterisation

The main production processes are electrolysis of magnesium chloride melts (made from resources like seawater and dolomite) and the metallothermic reduction of magnesium oxide with a share of 80% and 20%, respectively for the total production (Hoy-Petersen et al. (1999)). The different producers in the world use different processes. Fig. 5.1 shows a block diagram for the process used by Norsk Hydro that is investigated here. Magnesium is produced from seawater and dolomite. The production of  $\text{Mg}(\text{OH})_2$  includes calcination of dolomite, mixing with sea water and precipitation and filtration of  $\text{Mg}(\text{OH})_2$ . Thereafter  $\text{Mg}(\text{OH})_2$  filter cake is calcinated to  $\text{MgO}$ . Water free  $\text{MgCl}_2$  is prepared through pelletisation and chlorination of  $\text{MgO}$ .  $\text{MgCl}_2$  is electrolysed and ingots are produced in the foundry (Haagensen et al. (1996)).

Fig. 5.1 Block diagram of the dolomite and seawater process for magnesium production in Porsgrunn, NO (Haagensen et al. (1996))

## 5.1 Life Cycle Inventories

The inventory is split up into the primary production of magnesium and the further production of magnesium alloys. Then the manufacturing of diecastings is investigated. The infrastructure for magnesium production is assumed roughly.

### 5.1.1 Magnesium

The life cycle inventory investigates the production of magnesium from seawater for a modern production plant based on data from a Norwegian producer. All processes from seawater uptake until the magnesium leaves the plant are included in the inventory.

Energy is used for the preparation of dolomite lime, making  $\text{MgCl}_2$  cell feed from seawater and acid generation. Tab. 5.1 shows an overview for the energy requirements of magnesium production investigated by different authors. Different methodologies are used for the reporting of the energy requirements. Large differences exist for the reported energy requirements for the production of one kilogram magnesium. But, it has to be considered that some of the data have been investigated in the seventies. Thus a higher energy efficiency (a lower specific energy consumption) can be assumed for today's production.

**Tab. 5.1 Energy requirement of magnesium production as investigated in different studies. It has to be noted that assumptions for the calculation of the total energy requirements vary among different studies**

<sup>1</sup> Johanna Öster Haagenzen (Norsk Hydro, email communication 10.8.2000): The total energy demand for the production of pure Mg, including hydro power electricity, fossil fuel and other sources such as steam. The system boundary is from cradle to gate for "all" raw materials (life cycle perspective). This means that production of hydropower electricity is included in the 144MJ/kg, as well as extraction, production and transport of fossil fuels and so forth.

The inventory for the production of magnesium is mainly based on the environmental reports of Norsk Hydro for the year 1998<sup>2</sup> and on an LCA for the production of magnesium and magnesium diecastings by Norsk Hydro. Tab. 5.2 shows the results of the cumulative life cycle inventory published by Norsk Hydro for magnesium and magnesium die-castings (Albright & Haagenzen (1997); Haagenzen et al. (1996); Hydro Magnesium (1999a); Hydro Magnesium (1999b); Norsk Hydro (1999)). There is no explanation for the origin of some of the emissions, e.g. dioxins.

Production data are proprietary information. Therefore, these reports present only aggregated figures of the life cycle inventory. Thus it was unavoidable to disaggregate some data with uncertain assumptions or use cumulative data in order to achieve an inventory table for this study.

**Tab. 5.2 Cumulative energy consumption, direct emissions and waste data for the production of 1kg magnesium and AZ91 part from die-casting at Norsk Hydro. All stages in the life cycle from cradle to gate are considered in the inventory data for the alloys (Albright & Haagenzen (1997); Hydro Magnesium (1999a); Hydro Magnesium (1999b))**

The newest figure for the cumulative energy use of total 144MJ/kg (Albright & Haagenzen (1997)) is used. This figure has to be disaggregated to the type of energy uses. It is assumed that about 60% of the energy is delivered by electricity produced in Norway with a conversion efficiency of 82% (according to the ratios shown in Tab. 5.2). Other energy uses are steam consumption, the use of gas and due to the transports. This is estimated with 40% or 49MJ cumulative energy demand and a conversion efficiency of 67%. Thus 39MJ/kg of natural gas are used. The uncertainty of the data for the energy use is high as the summary in Tab. 5.1 shows because a full disaggregating of the found data is not possible.

An important factor for the environmental impacts is the use of SF<sub>6</sub>. It is used to protect molten magnesium from oxidation in the cast house, in the production of ingots and at the diecaster. Sulphur dioxide has been known to fulfil this function for a long time, but SO<sub>2</sub> is toxic in higher concentrations and in contact with humidity it will enhance corrosion of steel equipment. The quantities used in different

<sup>2</sup> Environmental information on <http://www.magnesium.hydro.com/> (26.7.2000). The facility in Porsgrunn was closed down 1st of April 2002. A new activity has been established in a part of the old factory. This new remelting facility is called Hydro Magnesium Alloys. Process scrap from magnesium users and pure magnesium from China are used to produce magnesium alloys (Personal communication, Liv Kari Sivertsen, 14.5.02).

plants varies between 0.1kg and 11kg SF<sub>6</sub> per ton produced magnesium components. The use of SF<sub>6</sub> for die-casting is not included in this figure (Gjestland et al. (1996)). Norsk Hydro has reduced the emissions from formerly 4kg/t to 0.7kg/t in 1998.<sup>3</sup> Estimates for the worldwide average specific consumption vary between 1.3kg/t and 7kg/t (Maiss & Brenninkmeijer (1998:3084)). We assume an average emission figure of 2.9kg/t for the magnesium production with data for the Norsk Hydro plants (0.7kg/t, 34% production share) and other plants (4kg/t).

The inventory for other emissions (e.g. SO<sub>2</sub>, dioxin, chlorinated hydrocarbons to water) is based on the data published in the environmental reports of Norsk Hydro (Tab. 5.2, Norsk Hydro (1999)). Charcoal is used for the chlorination of magnesia in an amount of 0.45kg/t (Hoy-Petersen et al. (1999:562)). The import from Asia by ship has been considered for this material. The theoretical emission of 1.32kg CO<sub>2</sub>/kg magnesium has been calculated from the charcoal use which is used as a reduction agent. The unit process raw data and data quality indicators for magnesium production are shown in Tab. 5.3. Transport of raw materials have been estimated with standard distances.

Large uncertainties exist for data on energy use and SF<sub>6</sub> emissions during magnesium production. For the energy use and the SF<sub>6</sub> emission a literature review has been used to estimate the standard deviation. The highest uncertainties exist for the SF<sub>6</sub> emissions which might be as high as 11kg/t. Emission data are used for cumulative emissions. Thus they overestimate the direct emissions in an unknown range.

**Tab. 5.3 Unit process raw data and data quality indicators for the production of magnesium. References and assumptions for the inventory are presented in the text.**

<sup>3</sup> Johanna Öster Haagenen (Norsk Hydro, email communication 8.8.2000): The total amount of SF<sub>6</sub> is depending on the total weight of magnesium handled. Norsk Hydro is in the process of changing production routines and SF<sub>6</sub> will be phased out. Hydro is also selling SO<sub>2</sub> diecast equipment and competence to diecasters and is offering service. Some diecasters have never used SF<sub>6</sub> and are still using SO<sub>2</sub>.

### 5.1.2 Magnesium Plant

The land use area and building size for a magnesium production plant has been estimated roughly with 1km<sup>2</sup> from a photo of the Norsk Hydro factory in Porsgrun.<sup>4</sup> Land transformation has been calculated according to standard methodology. The unit process raw data and data quality indicators for the magnesium production plant with an annual production capacity of 100 000t and a life time of 50 years are shown in Tab. 5.4. Data for the necessary equipment (likely also metals and bricks) were not available. They can be considered to be not important in comparison to the amount of produced magnesium.

**Tab. 5.4 Unit process raw data and data quality indicators for the magnesium production plant and data quality considerations.**

### 5.1.3 Magnesium-Aluminium Alloys

#### AZ91D

The magnesium alloy AZ91D (also known as M11916 or DIN GD-MgAl9Zn1) is the most common one for the production of die-castings. It contains 9.1% aluminium and small amounts of copper, zinc and manganese. Environmental impacts of production are only known from a summarized inventory (Albright & Haagensen (1997)). The inventory data derived from this investigation is shown in Tab. 5.5. The energy use has been disaggregated in the same way as for magnesium. Inventory data for the infrastructure are not considered as it is assumed that the production will take place in the magnesium production plant. Specific data for the inert gas use were not available. It can be assumed that it is not much more than for the pure magnesium (which is already included in the inventory).

**Tab. 5.5 Unit process raw data and data quality indicators for the production of magnesium alloy AZ91. References and assumptions for the inventory are presented in the text.**

## AlMg3

The production of AlMg3 (AA 5754 or EN AW-5754) is also investigated with the content of different metals used for the alloy. This aluminium alloy contains 3% of magnesium and little amounts of other metals (Lang (1999:9)).

The additional cumulative energy for producing the alloy is 7MJ/kg (conversion efficiency estimated with 82%) and it is assumed that it is delivered by the electricity mix of the aluminium industry. Transports are considered for the alloying metals but not for the main ingredients, as it is assumed that the alloy production is close to the magnesium or aluminium production plant. A material loss of 1.5% during production (assumed by Albright & Haagenen (1997 for magnesium alloys)) is considered for the inventory. It is assumed that the production takes place at the magnesium (or aluminium) production plant. Thus an additional infrastructure is not considered. The inventory is shown in Tab. 5.6. Information for further magnesium alloys can be found in the handbook of KAMMER *et al.* (2000)).

**Tab. 5.6 Unit process raw data and data quality indicators for the production of magnesium aluminium alloy AlMg3. References and assumptions for the inventory are presented in the text.**

### 5.1.4 Magnesium Die Castings

The diecasting process is used for the production of metal parts in a predefined form. SF<sub>6</sub> is also used during the die casting process in order to prevent molten magnesium from oxidation. Different authors have investigated the SF<sub>6</sub> use. GJESTLAND *et al.* (1996:39) reported that up to 1kg SF<sub>6</sub> per ton of Mg component might be used and emitted during the die casting process. In Germany, magnesium die casting producers used between 0.25 and 10 kg SF<sub>6</sub> per ton of magnesium or in some cases only SO<sub>2</sub>. The average use in 1995 and 1996 was 4.3 and 2.4 kg/t, respectively. Due to the decreasing amounts used, a prognosis assumed that until 2000 the average use will decrease to 1 kg/t (Schwarz & Leisewitz (1996:41)). For Swiss die casters the amount of SF<sub>6</sub> is reported to be 4kg SF<sub>6</sub>/t Mg-die castings. This is equal to an annual amount of 120kg (Klaus & Dinkel (1999:41)). A producer of die casting equipment<sup>5</sup> quantifies much smaller values for the usage of SF<sub>6</sub> and SO<sub>2</sub> with 0.012 to 0.018kg SF<sub>6</sub> and 0.049 to 0.075kg SO<sub>2</sub> per tonne of magnesium. These data could not be verified. For our inventory we assume based on the literature data 1kg SF<sub>6</sub>/t.

The cumulative energy use required to produce a finished die casting, including normal processing efficiencies, amounts to 21-45MJ/kg or 1.9-4.1kWh electricity/kg (Wilson *et al.* (1995:660)). It is as-

<sup>5</sup> RAUCH Fertigungstechnik, Austria, 22.8.2000, <http://www.rauch-ft.com/englisch/magnes/gas.html>.

sumed that only electricity is used (2.22kWh/kg). The inventory for die castings is shown in Tab. 5.7. Data for the infrastructure were not available.

**Tab. 5.7 Unit process raw data and data quality indicators for magnesium die-casting. References and assumptions for the inventory are presented in the text**

### 5.1.5 Recycling of Magnesium

The possibilities for the recycling of magnesium are described by KAMMER *et al.* ( (2000:49ff)). To-day about 17% of the magnesium supply is produced by recycling of magnesium wastes. Mainly pure wastes with a known composition are used for the recycling. The recycled magnesium is used mainly during the production of aluminium, iron and steel as a desulphurisation or reduction agent.

The use of electricity for the recycling is much lower than for the production of primary magnesium. KAMMER *et al.* ( (2000)) estimated it to be only 3 kWh/kg in comparison to about 20 kWh/kg for the primary production. Different processes can be used depending on the type of input material. The processes need normally also a protecting gas like sulphur hexafluoride, but the tendency is to use SO<sub>2</sub> to reduce the greenhouse gas emission.

Due to substantial lack of data we refrain from presenting unit process raw data for the recycling of magnesium. One might use the figures for magnesium and reduce the energy use to one-tenth in a first assumption. Other impacts especially for the SF<sub>6</sub> emissions can be expected to be about the same.

## 5.2 Data Quality Considerations

The simplified approach with a pedigree matrix has been used for calculating most of the standard deviations. Large uncertainties exist for data on energy use and SF<sub>6</sub> emissions during magnesium production. For the energy use and the SF<sub>6</sub> emission a literature review has been used to estimate the standard deviation. The highest uncertainties exist for the SF<sub>6</sub> emissions which might be as high as 11 kg/t. Also the value for transport distances of materials is very uncertain.

## 5.3 Conclusions

The environmental impacts of magnesium production have been investigated as a unit process over the life cycle from raw material extraction until the gate of the factory. The investigation is based on environmental data provided by a producer and on a literature research. High uncertainties still exist for the average energy and SF<sub>6</sub> use in magnesium industry. The inventory can be used in life cycle assessment for complex products where magnesium or metal alloys are used.

|                      |     |                            | The production of AlMg3 is investigated with the content of different metals used for the alloy. This aluminium alloy contains 3% of magnesium. | Production plant for magnesium with an annual capacity of 100'000t and a life time of 50 years.  | Large uncertainties exist for data on energy use and SF6 emissions during magnesium production. This inventory describes an assumption for the average production. | The magnesium alloy AZ91D is the most common one for the production of die-castings. It contains 9.1% aluminium and small amounts of zinc and manganese. Environmental impacts of production are only known from a summarized inventory. It is assumed that magnesium for this alloy has been produced in a new production plant. | Large uncertainties exist for data on energy use and SF6 emissions during magnesium diecasting. This inventory describes an assumption for the average production. |

EMPA Dübendorf, Swiss Centre for Life Cycle Inventories, Dübendorf, CH, Online-Version under: [www.ecoinvent.ch](http://www.ecoinvent.ch).

Final report of updated Swiss National Life Cycle Inventory Database "ecoinvent", version 2.1

## Comments on version 2.1

This part corresponds to the original report in Althaus et al. (2004). Chapter “6 Cumulative Results and Interpretation” of the original report has been deleted for the current update.

Besides of these reported changes no alteration of the original text took place for version 2.0. Some of the reference flow names have been changed compared to the preceding versions. They have been updated with the actual names of version 2.0.

For version 2.1, a new model for emissions of sulfidic tailing disposal is introduced. The dataset “disposal sulfidic tailings, offsite” is changed and the report adapted accordingly.

## Summary

In this part, the modelling of disposal of sulphidic and non sulphidic tailings and overburdens and that of mine and smelter infrastructure is described. These modules are used in the production of different non ferrous metals.

The long term emissions from sulfidic tailings due to acid rock drainage are believed to be of major importance for the LCI of metals from sulphidic ores. For version 2.1 a dedicated tailings disposal model was taken up.

# 1 Introduction

Several production processes of the non ferrous metal industry are similar to each other. Namely the winning of the metal bearing ore and the beneficiation processes depend mainly on throughput of minerals. Process specific differences are rather linked to the type of metal carrying ore than to the desired metals present in the ore. Most of the non ferrous metals originate from sulphidic ores which present different implication for processing than e.g. oxidic ores. Different metals, e.g. nickel and copper, often are coexistent in the sulphidic ore and are won jointly by the same metallurgical processes. Also infrastructure of mines, beneficiation facilities, metallurgical plants and refineries do not differ greatly from one metal winning process to another. Due to these similarities several auxiliary processes and infrastructure are not differentiated further in ecoinvent. The modelled disposal-processes for overburden and tailings are valid for all non-ferrous-metal industries. The only difference is made for sulphidic tailings, which undergo acid rock drainage – reactions with enhanced leaching and considerable acidification. In v2.1 of ecoinvent a dedicated model for sulfidic tailings was introduced.

## 2 System Characterisation

In this chapter several auxiliary processes of the non-ferrous metal industry are discussed:

- disposal processes,
- land use and
- infrastructure.

Fig. 2.1 gives an overview over these impacts discussed in this chapter and the modules in ecoinvent they are inventoried in. Basically three types of activities can be distinguished when inventorying mining operations.

**Operation:** Extraction of ore effects a direct type of impact. For each tonne concentrate excavated a certain amount of land is transformed to become an extraction site for a certain time. Additionally infrastructure like hauling trucks, bucket wheel excavator and conveyor belts are required. The demand in these resources (land) and processes (infrastructure) are inventoried directly within the respective mining module, they are direct proportional to the mass<sup>1</sup> of ore processed. Also the leaching of metal from ore is considered as extraction, the land use for leaching – which is considerable – therefore also is where appropriate inventoried within the mining module. In the case of froth flotation the ore is ground in mills. The mill heads and jaws are severely strained, the consumption in these parts is also inventoried as direct impact in terms of demand in austenitic manganese steel (2.1.2 Direct land use).

**Infrastructure:** The infrastructure is inventoried as separate modules, each for underground mine, open pit mine, beneficiation and smelter. These are pure infrastructure modules and comprise the building of the mining, beneficiation, etc. facilities, roads, docks etc inclusively the disposal. These modules do not refer to the direct impact in the mineral extraction site where the ore is mined, but to the facilities for ore-processing, maintenance buildings, staff accommodation, etc. The functional unit is infrastructure units per kilogram raw-material processed, thus the functional unit refers to the input (2.2 Infrastructure in the non-ferrous metal industry).

**Tailings / overburden:** The extraction of metal ore is actually a concentration process. First, the ore has to be separated from rock, be it to access the veins, be it to clean the extracted material from unwanted fractions. This unwanted material is referred to as overburden. In a second step, the metal bearing ore is concentrated further using different mechanical and/or chemical beneficiation methods. The unwanted mineral fraction is referred to as tailings. Tailings consist of ground mineral and often form a slurry after separation, which is disposed in large ponds lined with dams. Apart from the considerable land use, also emissions arise from disposing the material. It is assumed, that the disposed material is alien to the place where it is disposed (off-site) and therefore virtually all of the substances leached over time have to be regarded as emissions. The functional unit of these modules is the mass of tailings or overburden disposed (c.f. 2.3 Disposal of Overburden and Tailings).

**Rehabilitation of tailings:** In this study no rehabilitation of the tailings and overburden disposal site is considered. It is assumed, that the disposal site never will turn to its natural state and consequently no energy and materials are used for rehabilitation. This situation probably presents the norm in a global view.

**Kommentar [gd1]:** d.h. infinite land use?

<sup>1</sup> This assumption might be biased in the case of infrastructure like processing plants. The choice of the material's volume would probably more correct. Since the density is not exactly known in most cases and the difference in densities is expected to be small from ore to ore, the mass is chosen as functional unit.

Fig. 2.1 Overview over infrastructure, land use and rehabilitation of the mineral extraction site. Rehabilitation of infrastructure (production site) and tailings are not considered in this study.

## 2.1 Land Transformation and Land Use in Mining and Beneficiation

The effects of mining and beneficiation to land resources can be differentiated into three types:

- Land used by facilities (roads, buildings, stationary equipment)
- Direct land use through exploration and beneficiation (excavation, eventually heap leaching)
- Land used for disposal purposes (stockpiles, tailings)

These three effects are treated in ecoinvent in different modules. As no detailed data for the working of different ore was available, the same values were used for all the modules dealing with non-ferrous metals.

### 2.1.1 Facilities

The land use of the facilities comprise roads, buildings, stationary equipment like screens, feeder, conveyor belts, docks, crusher, mills, cyclones, etc. A good dependency of the Area covered with the yearly production capacity of the operation is found in Martens et al. (2002). Results and assumptions are shown in Tab. 2.1. This land use is inventoried in the infrastructure modules

- “non-ferrous metal mine, surface”
- “non-ferrous metal mine, underground”
- “non-ferrous metal smelter”

**Tab. 2.1** Specific land use by facilities in open cut and underground mining. These figures comprise Beneficiation facilities. Data for land use is a function of the production capacity<sup>2</sup> as described in (Martens et al. (2002)).

| Infrastructure        | Unit                | Open cut   | Underground |
|-----------------------|---------------------|------------|-------------|
| Yield, capacity       | t/a                 | 400'000    | 400'000     |
| Lifetime              | a                   | 50         | 50          |
| Land use              | m <sup>2</sup>      | 122'011    | 184'830     |
| Total yield, lifetime | t                   | 20'000'000 | 20'000'000  |
| Specific land use     | m <sup>2</sup> /t   | 0.0061     | 0.0092      |
| land occupation       | a m <sup>2</sup> /t | 0.305      | 0.462       |

### 2.1.2 Direct land use

According to Martens et al. (2002) a total land transformation of 20 m<sup>2</sup> per thousand tonnes mined copper ore is effected. This figure of 0.02 m<sup>2</sup>/t raw ore is taken as proxy for all non ferrous metals except for aluminium, tin and magnesium. It includes the effects of tailing ponds (42% of the land transformation), leaching heaps (17%), stockpiles (13%), open cuts (10%), facilities (16%) and lowering of the ground through underground mining (2%), covering world-wide mining activities including open cut (80% of the ore) and underground (20%). In this study the lowering of the ground is assumed not to be ecologically effective. Where heap-leaching is effectuated, the value for land transformation adds up to 0.0059 m<sup>2</sup>/t ore, whereas no direct land use for underground mining is considered (Tab. 2.2).

**Tab. 2.2** Land use through direct exploration of the mine. A lifetime of 30 years was assumed. The lowering of the ground through underground mining is not regarded as ecologically relevant and thus is not inventoried.

| Specific land use | open pit              |                         |
|-------------------|-----------------------|-------------------------|
|                   | transformation        | occupation              |
| Unit              | m <sup>2</sup> /t ore | a m <sup>2</sup> /t ore |
| Leaching heaps    | 0.00340               | 0.102                   |
| Open cut          | 0.00250               | 0.075                   |
| Total             | 0.00590               | 0.177                   |

<sup>2</sup> Log-log dependency:  $\text{Area}_{\text{open cut}}[\text{m}^2] = 23.869 \text{ Yield}_{\text{open cut}}[\text{t/a}]^{0.662}$  and  $\text{Area}_{\text{underground}}[\text{m}^2] = 0.322 \text{ Yield}_{\text{underground}}[\text{t/a}]^{1.028}$

### 2.1.3 Land use for waste rock disposal

In mining large fractions of overburden has prior to extraction to be disposed on stockpiles. For open cut operations the ratio between ore and overburden ranges e. g. for nickel typically from 0.3 to 2 (Hilbrans & Hinrichs (1999)). Tailings consist of the unwanted part of the ground ore (gangue) which is separated and usually is disposed as slurry in large ponds.

According to reported values for tailing ponds in IPPC (2002), an average land use of 0.051 m<sup>2</sup>/t and 6.62 m<sup>2</sup>a/t tailings disposed is calculated (Tab. 2.3) assuming an average mine operation of 30 years. The land transformation is assumed to be from “unknown” to “disposal site” for the duration of 100 years after which it is rehabilitated in a natural way. Assuming that the whole disposal area for the tailings and overburdens has to be cleared prior to any disposal activities, i. e. at the very start of the mine operation, the duration of the whole land use is 130 years.

**Tab. 2.3 Assumptions and calculations regarding land use and eventual rehabilitation from tailings. Duration of mine operation phase is 30 years. The tailings are covered with 0.8 m of earth and a density of 0.8 kg / l. After 100 year the disposal site is assumed to be rehabilitated naturally.**

## 2.2 Infrastructure in the non-ferrous metal industry

For the inventory of the aluminium production a detailed estimation of the sintering and electrolysis has been made in this study. These figures together with the inventories of the blast furnace, electric arc and blast oxygen converter of the inventory of the iron production built the base for infrastructure estimation of the non-ferrous metal production.

Since it can be assumed that the environmental impact due to infrastructure is very small compared to the energetic intensive, high-throughput production processes in concern, a non-specific module for mining, beneficiation, smelter and refinery is set up. Tab. 2.4 gives an overview over the process-steps involved in the non-ferrous metal industry. Depending on the prevailing of a process step and raw material input the factor is calculated.

Tab. 2.4 Process-steps involved in the non-ferrous metal modules.

| metal / ore      | Raw material    | concentration | yield    | mining under-ground | mining surface | Beneficiation | sintering | Hydro-metallurgical | Metallo-thermal     | electric arc furnace | pyrometal lurgical blast | refinery |

### 2.2.1 Process description

The following paragraphs discuss the main process steps in the non-ferrous metal industry.

**Mining:** Mining is differentiated into open-pit mining and underground mining. Depending on the hardness, the ore can be mined in some cases without explosives. Such soft ore is directly extracted with bucket loader, whereas hard material has to be blasted. Techniques in underground mining do not differ vastly from those in surface mining, especially if the layer mined is high enough for big vehicles. Usually vehicles used underground tend to be smaller with adaptation to low height and low off-gas emissions. Another difference between surface and underground mining is the need for air circulation and cleaning. Hence, beside a few specific features – like hoists in underground mining – no major differences exist.

**Beneficiation:** Most ores are subjected to a first concentration step after being mined. In some cases the only beneficiation possible is a mere classification by size and/or gravity, which yields only a little concentration effect. The beneficiation step of these ores is not considered in this study. In most other cases a beneficiation including a froth flotation is carried out: After mining, the ore is first ground. In a next step it is subjected to gravity concentration to separate the metallic particles from the metal bearing minerals. After this first concentration step, flotation is carried out to remove the gangue from the sulphidic minerals. For this lime and several organic chemicals are added. Tailings usually are led to tailing heaps or ponds. Flotation mills consist of several crushers and screens, ball and rod mills, belt feeder, pumps, filters, float cells, thickener and usually a magnet, dust collector and buildings – truck shop, crusher building, concentrator building and reagent building. In this setting it resembles the hydroxide plant in the aluminium production where the ore also is ground and cleaned from gangue. An example of a medium sized beneficiation plant (flotation mill) is shown in Fig. 2.2.

The beneficiation infrastructure in this study is not covered with a specific module, but approximated with the inventory of the aluminium hydroxide plant, which itself is a beneficiation (specifications: Medium sized plant. Output: 1'220'000 t/a, life time: 50 years). If the inventory of this module is related to its input rather than to its output, the demand has to be corrected by a factor of 1.40, i. e. the production of 1 kg aluminium hydroxide requires 1.4 kg bauxite (ore in the aluminium production). The beneficiation of 1 kg ore therefore requires  $8.40 \cdot 10^{-12}$  units of the module “aluminium hydroxide, plant”. IPPC (2001) reports a demand of 300 g steel due to abrasion of the mill jaws per tonne ground ore, the steel being inventoried as “chromium steel 18/8, at plant”.

**Metallurgy:** The process routes to produce different non-ferrous metals are very divers. As seen in Tab. 2.4 the metallurgical steps usually consist of a sintering / roasting step followed either by a pyrometallurgical or an electrolytic step. The pyrolytical step usually consists of a smelter followed by a converter. In some cases an additional refining step is necessary to yield the grade necessary for trade. The products usually leave the plant after re-melting, casting or preparation steps as powder, ingots, etc. An example of a metallurgical process is given in Fig. 2.4 (copper production).

**Refining:** Some metals like the platinum group metals are won from residues from electrolysis and other residues like dross or from scrap containing some metal values. These Refineries resemble chemical plants where metals subsequently are separated from each other using techniques as solvent—solvent extraction or precipitation/filtration.

Refineries are approximated with the module of “chemical plant, organics”.  $4 \cdot 10^{-10}$  units of this infrastructure module are afforded per kg chemicals. This value is taken also in this study for all those processes, where the refined metal is won by a cascade of purification processes. This is true for the Platinum group metals. For reasons of transparency, no specific module is made for the non-ferrous metal industry. If appropriate in a module, the refinery infrastructure is inventoried as “chemical plant, organics” and clearly is marked as proxy.

**Fig. 2.2** Picture of a flotation mill with crusher, concentrator, thickener and several flotation cells. The output of the mill is stated to be 6'000 – 10'000 t per day (around 2.5 Mt per year).

### **2.2.2 Non-ferrous metal mine, underground in Ecoinvent**

The infrastructure use for a mine is estimated in Tab. 2.5. It comprises land use for mining facilities, production of buildings and equipment including their disposal. No rehabilitation of the industrial site is considered. The values for the surface mine differ only in specific points from those for the underground mine. The data represent a rough estimate that is based on qualitative information like pictures and process descriptions of actual mines.

Land use and occupation is chosen as explained in 2.1.1 Facilities, it thus comprises also the beneficiation facilities.

### **2.2.3 Non-ferrous metal mine, surface in Ecoinvent**

The infrastructure use for a mine is estimated in Tab. 2.6. It comprises land use for mining facilities, production of buildings and equipment including their disposal. No rehabilitation of the industrial site is considered. The values for the surface mine differ only in specific points from those for the underground mine. The data represent a rough estimate that is based on qualitative information like pictures and process descriptions of actual mines.

Land use and occupation is chosen as explained in 2.1.1 Facilities, it thus comprises also the beneficiation facilities.

Tab. 2.5 Infrastructure mine, underground. Assumptions made and inventory chosen.

| Mine, underground                                                                                    | Demand      | Unit           | Material / Module          | Life time | Life time demand |

## 2.2.4 Non-ferrous metal, smelter in Ecoinvent

The infrastructure for the metallurgical step is inventoried as one unspecific module valid for a wide range of metal industries, including hydro- and pyrometallurgical processes. Its functional unit is [kg] ore concentrate in input. In this study the infrastructure of the metallurgical step is approximated roughly with:

1. sintering / roasting furnace (rotary kiln)
2. electrolysis plant (50% of the cases) and
3. blast furnace, followed by a electric arc converter (50% of the cases)

These steps build up the system of metallurgical facilities to process a certain amount of ore concentrate. This is shown in Fig. 2.3. With an average input of 6'775'000 t ore concentrate this module is required in the inventories with a factor  $1.48 \cdot 10^{-10}$  per kg concentrate processed.

Step 1) is inventoried using the infrastructure of the aluminium oxide plant, which itself represents a roasting (oxidising) step. Therefore the module “aluminium oxide, plant” (Medium sized plant. Output: 800'000 t/a, life time: 50 years) is chosen, which has to be scaled by factor 8.5 to produce the roasted concentrate required.

Step 2) represents the hydrometallurgical process route for which a fraction of 50% of the concentrate roasted is chosen, i. e. as an approximation it is assumed that one half of the metal is produced hydrometallurgically. The required infrastructure is approximated with the electrolysis of aluminium, “aluminium electrolysis, plant” (Medium sized plant. Output: 130'000 t/a, life time: 50 years. Site is shared with casting plant. Total land use is allocated 50% to electrolysis, 50% to casting). Also this module has to be scaled with a factor of 17.

Step 3) is also weighted with 50% and includes two steps, the smelting and a subsequent converting. Here too, existing infrastructure modules from the iron industry are chosen as proxy for the smelting furnace and the converter. In this case it is the module “blast furnace” (Assumptions for medium sized plant. Output: 1'500'000 t/a, life time: 50 years. Site is shared with BOF converter.) and “blast oxygen furnace converter” (Output: 1'500'000 t/a, life time: 50 a). The yield for the blast furnace is 91% (including sintering and smelting), yielding a factor of 1.22.

In most cases – as shown in Fig. 2.4 – the off-gas is captured and the sulphur dioxide from the roasting / smelting is used in the production of sulphidic acid. It is assumed that 0.7 kg  $H_2SO_4$  is produced from the off-gas of 1 kg concentrate roasted (Ayres et al. (2002)). Since most of the ores are of the sulphidic type, and also non-sulphidic ore smelters have elaborate abatement technologies for off-gas, additional 1.90 units “chemical plant, organics” (lifetime: 50 a; production: 50'000 t / a).

Fig. 2.3 Scheme of the infrastructure modules building up the metallurgical step. The modules are scaled to a specific throughput, which is set to be 1'500'000 t output per year at the converter. The modules for sintering/roasting, electrolysis and blast furnace are scaled to meet the requirements. The concentration in the ore is calculated to be 39%, which is true for many metals.

Fig. 2.4 Example of a pyrometallurgical process step in the copper industry<sup>3</sup>. Off-gas is captured in the sulphuric acid plant. The smelting furnace is followed by a flash converter, the metal leaves after a final refining step. This final refining is part of the metallurgical step and is not to be confused with the process denoted as refining in this study, which is more of a chemical plant than a smelter.

## 2.3 Disposal of Overburden and Tailings

This chapter deals with ecological burdens due to the disposal of sulphidic overburden and tailings from mining and Beneficiation. For modelling these deposits, three separate modules are generated:

- “disposal, sulfidic tailings, off-site”
- “disposal, non-sulfidic tailings, off-site”
- “disposal, non-sulfidic overburden, off-site”

Major impacts are emissions to water, land transformation and land use. Because of the acidic environment in the tailings, a considerable leaching occurs, whereas the overburden remains more or less inert. Overburden, which is refilled, is considered to have no ecological burden.

### 2.3.1 Process and infrastructure

To access an ore deposit, overburden has to be removed first. This material does not contain ores, therefore is not processed and is usually deposited as crushed rock or finely ground meal but chemically unchanged, either in the mining pit (backfill) or on piles. Overburden often is used as building material for the lining of the tailings ponds.

The mined ore then is separated from the gangue, i.e. from the unwanted minerals. This usually is done by grinding and flotation. The resulting slurry then is transported to so-called tailings stacks. This disposed material covers a sometimes considerable area, it often contains sulphur, ore-borne metals and different reagents from the beneficiation step. The sulphide minerals in the tailings are oxidised to sulphuric acid, which leads to a low pH and high degree of leaching of metals. Tailings stacks are about 20 m in thickness. Its borders are lined by dams and the excess water is led to a cascade of ponds for further settling of solids. In the tailings ponds the slurry consequently sediments and thickens. If the dam height is reached, the dams usually get enhanced, finally up to several tens of metres high (IPPC (2002)).

After the mines operation phase, these ponds are usually rehabilitated. Often the tailings pond is covered with earth, while the cleaning ponds stay to form natural surface waters.

### 2.3.2 Emissions

#### Water

The overburden is assumed to emit no relevant pollutants. The low pH in sulphidic tailings however is a distinctly different chemical environment than the overburden's original location. Also tailings are a finely ground rock meal, mixed with water and exposed to atmospheric oxygen. This leads to additional emissions from formerly inert minerals.

The tailings are often subject to acid rock drainage (ARD), where sulphur oxidises in the presence of metal, water and oxygen promoted by bacterial activity to form sulphuric acid. The reactions are complex and persistent. Mines worked by the Romans in Spain and the Vikings in Scandinavia continue to generate ARD today. This makes it an even bigger issue than cyanide leakage, which is chemically unstable and does not persist in the environment. Once exposed to oxygen ARD reactions on mineral surfaces will continue for thousands of years.

#### Air

No considerable emissions to air are reported. In arid climates wind-blown erosion can be a relevant emission pathway for tailings.

### 2.3.3 Disposal of Sulphidic Tailings in ecoinvent
