Tailings are a slurry waste produced during metal ore refining (beneficiation). Tailings are usually poured into tailings impoundments, where water is removed and the slurry solids are stacked. Tailings can contain sulfides, which are biochemically oxidised to sulfuric acid. The acidic pH then promotes washout of many metals (Acid Rock Drainage, ARD). Large masses of tailings are produced per kilogram metal especially if ore grades are low. Tailings impoundments represent a considerable environmental burden in the primary metal process chain, because tailings contain large amounts of toxic metals and large masses of tailings are produced: the current annual worldwide production of all types of tailings is estimated to be several hundred million metric tonnes per year, which surpasses the mass naturally eroded from the earth's surface by rivers (Gardner & Sampat 1998). In the ecoinvent database v2.0 typically sulfidic tailings are produced in production of primary copper, nickel, zinc, lead, cobalt, molybdenum, and platinum group metals. Tailings from aluminium ore beneficiation (redmud) are heeded in the respective chapter. Tailings from uranium ore beneficiation is heeded in the nuclear process chain (ecoinvent report 6, part VII).

A dataset for sulfidic tailings was created in ecoinvent v1 in 2003. However, this dataset only included land use and land transformation aspects, but no emissions for a lack of reliable composition data and tailings deposit models. For ecoinvent v2 this data gap is filled with emissions data from a specifically designed tailings model. This complemented dataset should provide a first informed estimate of the full magnitude of sulfidic tailings burdens for non-ferrous metal products and encourage further research for more detailed models for the ecoinvent v3. In order to avoid overestimations, the modelling assumptions – within the ecoinvent framework – were chosen to be conservative. An extended report on the sulfidic tailings model is freely available online (Doka 2008).

#### Tailings landfill model

The tailings landfill model was based on the modelling framework applied in other ecoinvent landfill process models (ecoinvent report 13: Doka 2003). These models are based on a top-down approach. Literature data on measurements of deposited compositions and currently measured concentrations in landfill leachate are used to calculate the currently occurring emissions of the landfill. Heeding chief parameters like hydrology and pH development these emissions are then projected into the future. Thus these models incorporate physical and chemical conditions, while being rooted in the currently observed emission behaviour. More details on general modelling assumptions of these models can be taken from (Doka 2003). The resulting tailings model and its transfer coefficients are not applicable to other waste types.

A large database with literature data on tailings composition and measured tailings leachate concentrations mainly from copper, zinc, lead, nickel and molybdenum mining sites is assembled<sup>4</sup>. The geometric mean of established data is taken to represent a global average sulfidic tailings composition and leachate composition. The relation between leachate concentration and tailings composition quantifies how easily this particular element is transferred to the aqueous phase and thus how high its mobility is. To make comparisons with other landfill models, elemental transfer coefficients for the tailings landfill are calculated, although this is currently not necessary, as only one tailings material composition is considered here. Roughly 2600 individual data points are used to create the model of tailings emissions for 39 chemical elements.

---

<sup>4</sup> Data was taken from ATSDR 1997; ATSDR 2006; Boulet & Larocque 1998; Dorronsoro et al. 2002; Downing & Gravel 2006; EPA 1994; Garcia-Meza et al. 2006; Hadjibiros et al. 2005; Hernandez et al. 2007; IAEA 2003; IPPC 2004; Koerth 2002; Laliberte & Tremblay 2002; Lazar 2002; Matheis et al. 1998; McLemore et al. 2006; MIMI 2004; Muwanga 1997; Nash 2000; OK Tedi 2002; Robinson et al. 2004; Thoms 2006; Tyler et al. 2004; Van Zyl 2002; Wels et al. 2000; Ye et al. 2002

Based on acid-base balances, it is assumed that no pH-induced changes in leachate concentrations occur. I.e. the *currently observed* emission behaviour is taken to represent the *average long-term* situation. This is a conservative approach, since the literature data includes data from impoundments that have not, or not yet developed an acidic pH. The long-term mobility of metals tends therefore to be underestimated.

Chemical weathering of tailings depends on climate conditions. In wet climates large volumes of downward leaching through the tailings body are possible. In arid climates leaching is slow or in reverse direction, because water evaporation transports soluble tailings materials to the surface. Surface erosion by wind is a relevant emission pathway in arid climates (cf. Fig. 2.8). In this study, however, only emissions via bottom leaching are considered.

While the landfill models in (Doka 2003) were based on Swiss climate, for the tailings model the climate and precipitation that is relevant to tailings sites is heeded. Based on the location of the world's largest producers of sulfidic tailings, a weighted average precipitation rate of 770 mm/a was calculated (Spiess 2002, FAO 2000). In a global average situation, tailings deposits are rarely vegetated due to the extreme type of ground. Evapotranspiration of precipitated water is therefore neglected. It is assumed that tailings deposits are ideally constructed in such a way that mechanical erosion by surface runoff is excluded. All precipitation water therefore infiltrates the landfill body. All major mining sites are outside permafrost regions, so that a normal water circulation is possible. The height of the tailings landfill is assumed to be 50 meters. With a tailings density of  $2200 \text{ kg/m}^3$  a mass of  $110'000 \text{ kg}$  tailings is deposited per square meter tailings landfill surface. Thus, an amount of 0.007 litres precipitation water per kilogram tailings infiltrates annually.

Fig. 2.8 Wind blown tailings in Clayton mine, Idaho, USA (Hammarstrom et al. 2002)

Fig. 2.9 Nickel Tailings in Sudbury Ontario, Canada (Burtynsky 1996)

A part of the infiltrated water flows preferentially through the tailings. Due to the fine grain size of tailings, the amount of preferentially flowing water is assumed to be only 5%, and the residence time of preferential water is assumed to be 18 weeks ( $=T_p$ ). The water content of stabilised tailings is assumed to be 30 w-%. It is assumed that preferentially flowing water has little contact with the tailings materials and carries no pollutants from the landfill<sup>5</sup>. Based on model formulas given in Doka

<sup>5</sup> If landfills dry out periodically, then preferential water might wash out evaporites and be significantly burdened. This effect is not heeded here.

(2003:III.30ff.) it follows that the amount of effective, i.e. polluted annual leachate volume is 0.0067 litres per kilogram tailings ( $=V_{eff}$ ).

Transfer coefficients are calculated for two time horizons, 100 years (short-term) and 60'000 years (long-term). In Doka (2003) a long-term time frame of 60'000 years was chosen to represent an 'ecological planning horizon': by that time the Swiss midlands will probably be covered again with glaciers, that remodel the Swiss landscape. At that time the Swiss ecosphere will be redefined, creating new boundary conditions for environmental goals. The emissions over 60'000 years therefore represent a coarse mean expectation value of the burden inflicted on the ecosphere as we know it now and are concerned about. In other regions this ecological planning horizon might be dissimilar. Especially in tropical regions very long periods of climatic stability can be expected<sup>6</sup>. For simplicity a long-term time frame of 60'000 years for all tailings sites was chosen.

Due to lack of data, certain transfer coefficients are estimated by chemical similarity. Transfer coefficients for halogens are based on data from fluorine. Transfer coefficients for nitrogen are based on sulfur. Transfer coefficients for scandium are based on the arithmetic mean of antimony and selenium. Transfer coefficients for tungsten are based on the arithmetic mean of molybdenum and selenium. All these proxies are for completeness only and make up only very minor contributions to the LCIA results for this dataset (less than 0.1 percent).

Even after 60'000 years only a part of the deposited tailings are leached. With the modelled transfer coefficients roughly 8% of the toxic potential in tailings is emitted, and 92% are retained in the impoundment.

### Comparison with residual material landfill

The transfer coefficients of the tailings landfill can be compared with the transfer coefficients of a residual material landfill<sup>7</sup> from (Doka 2003), as shown in Fig. 2.10.

**Fig. 2.10 Comparison of short-term transfer coefficients for residual material landfill (x axis) and tailings deposit (y axis)**

<sup>6</sup> In such regions ecological planning horizons might be defined by very rare events like climate changes after meteorite impact (cf. Cretaceous-Tertiary impact winter 65 million years ago) or by very slow processes (glaciation after continental drift). For example, about 400 million years ago most regions that are tropical today were close to the south pole. However, currently tropical regions drift towards the equator and not towards the poles.

<sup>7</sup> The Swiss residual material landfill is for inert, inorganic waste materials sometimes solidified with cement.

Tab. 2.8 Average sulfidic tailings composition from literature survey

| Element | Content in tailings mg/kg (geomean) | Data points (n) | Geometric Standard Deviation |
|---------|-------------------------------------|-----------------|------------------------------|
| S       | 14600                               | 57              | 1670%                        |
| N       | 23.1                                | 3               | 11600%                       |
| P       | 493                                 | 85              | 384%                         |

It is apparent that oxianions have reduced relative mobility in the tailings deposit (red area in Fig. 2.10). Oxianions are more mobile at high pH values. Since residual landfills have high pH values, but tailings deposit often have low pH values, the modelled behaviour is realistic. On the other hand there is a cluster of elements with higher mobility in tailings deposits (blue area in Fig. 2.10), that contains elements that are easier soluble at low pH values. While the uncertainties in these coarse models are high, it is an encouraging fact that they succeed in depicting *chemically reasonable mobility behaviour*, without any information on such mobility characteristics being entered into the models beforehand. The results of the model are reasonable and not overly dependent on the variable nature of the fundamental data. Otherwise such clustering of elemental types could not be distinctly observed. It is a sign that the sample size of the applied literature data is large enough to represent *typical* tailings.

### **Tailings impoundment land use**

Land use is based on a generic final height of a tailings impoundment of 50 meters. Thus, per kilogram tailings with a density of  $2200 \text{ kg/m}^3$  a land area of  $9.1 \cdot 10^{-6} \text{ m}^2$  is necessary. The land is assumed to be converted from unknown origin to dump site. After an operational phase of 30 years, spontaneous restoration of a consolidated state is assumed to be reached after one hundred years. The total occupation time is therefore 130 years and the land occupation per kilogram tailings  $1.18 \cdot 10^{-3} \text{ m}^2\text{a}$ .

### **Outlook**

Representation of sulfidic tailings disposal in the ecoinvent database is still very coarse: there is only one single dataset for *any* sulfidic tailings deposit. Much remains to be done, which was not possible due to time and money constraints: in the future the tailings disposal inventory should be differentiated according to the mined metal, the tailings site climate and other important conditions.

### **Data quality**

Uncertainty in this dataset is high, but not only due to a high aggregation level resulting from a worldwide average. The subject matter is inherently uncertain due to the stochastic processes in the earth's crust, leading to very diverse ore bodies, and thus to very variable data relating to tailings even for one single mining site. Hence, the level of uncertainty is high and likely to remain high, even if in the future more differentiated tailings models for single sites or regions are created. The sample sizes for almost all relevant (toxic) elements are in the range of 80 – 140 data points. Presuming the literature data is representative, these sample sizes are large enough to yield significant LCIA results for the observed data variability.

The uncertainty range for the emission data is derived according to the procedures applied in Doka (2003). In a worst case, all tailings material will be weathered or eroded within 60'000 years. This worst case is taken to represent the upper confidence value of a lognormal distribution. Together with the inventoried mean emission, the geometric standard deviation is defined.

Rehabilitation and tailings management as it is done in certain parts, can alter the ecological impacts greatly. Due to the lack of reliable data, no deliberate rehabilitation is assumed here.

Tab. 2.10 Inventoried exchanges for the disposal of sulfidic tailings.

### 2.3.4 Disposal, non-sulphidic tailings, off-site in ecoinvent

The effects modelled in this module are

- land transformation
- land use

Tailings without considerable content of sulphur do not undergo ARD reactions. The pollution potential is therefore lower than in sulfidic tailings for the classic heavy metal pollutants. However also non-sulfidic tailings are mechanically compromised (ground into a dust), mixed with water and exposed to atmospheric oxygen. This can result in distinctly different behaviour compared to the original setting in the ore vein. No model for non-sulfidic tailings was created here, so no emissions to soil or water are considered, solely the land transformation and land use are modelled with similar figures as in 2.3.3.

The flux of this module and its representation in ecoinvent are presented in Fig. 2.12.

#### Data quality

Land use and occupation are calculated based on figures from only few sites. Rehabilitation and tailings management as it is done in certain parts, can alter the ecological impacts greatly. Due to the lack of reliable data, no rehabilitation is assumed here.

### 2.3.5 Disposal of overburden in ecoinvent

The effects modelled in this module are

- land transformation
- land use

Overburden is assumed to be piled on spherical heaps with a diameter of 20 m and a volume of 16'755 m<sup>3</sup>. With an in-situ density of 1.8 t / m<sup>3</sup> this is 0.0418 m<sup>2</sup> and 5.43 m<sup>2</sup>a per tonne overburden disposed. The land is assumed to be converted from unknown origin to dump site. Restoration of the natural state is assumed to be reached after one hundred years naturally, yielding an occupation of 130 years with the mine operation duration included.

No rehabilitation by human activities is assumed. Rehabilitation of coarse material often is done by re-vegetation. Per m<sup>2</sup> a mass of roughly 0.5 kg seeds would be necessary, which is 0.021 kg per tonne, transported over a distance of 100 km ( = 2.1 10<sup>-3</sup> tkm / t).

Overburden, which is refilled, is not inventoried at all.

The flux of this module and its representation in ecoinvent are presented in Fig. 2.13.

#### Data quality

Land use and occupation are calculated assuming a spherical heap. This can lead to overestimate the land occupation of bigger piles. Rehabilitation and tailings management as it is done in certain parts, can alter the ecological impacts greatly. Due to the lack of reliable data, no rehabilitation is assumed here.

Classen M., Althaus H.-J., Blaser S., Tuchs Schmid M., Jungbluth N., Doka G., Faist Emmenegger M. and Scharnhorst W. (2009) Life Cycle Inventories of Metals. Final report ecoinvent data v2.1, No 10. EMPA Dübendorf, Swiss Centre for Life Cycle Inventories, Dübendorf, CH, Online-Version under: [www.ecoinvent.ch](http://www.ecoinvent.ch).

## **Summary and Comments on version 2.1**

This part contains information and LCI of different metal forming and coating processes and with welding. The modules include only the processes themselves and not the metals being formed, coated or welded.

The part corresponds to the original report in Althaus et al. (2004). The chapters “Cumulative Results and Interpretation” of the original report have been deleted for the current update.

Note that the flow names in the tables displaying unit processes have not been updated to reflect the name changes with version 2.0. This namely affects the designation of transportation service flows.

Version 2.1 remains unchanged compared to version 2.0 except for the meta information to the process “zinc coating, pieces, adjustment per um”.

# 1 Introduction

This part deals with the forming and coating processes and with welding of different metals.

Metals, can be subjected to plastic deformation in the solid state by the application of external forces, i.e. it can be formed into new permanent shapes. Here, the term "forming" means the intentional and controlled change of the geometry of a work piece, usually from a simple geometry to a complex one with regard to the shape, size, accuracy and tolerances, appearance and properties. The mass, composition, and state of the material remain unchanged. If, however, the plastic limit is exceeded so that the change in geometry is not controlled, forming with defects occurs, and the desired product is not obtained. The phenomenon of plasticity results from the crystalline structure of metals. Their engineering and industrial use depends on forming technology (Kümmerling (1997)).

Coating of metals is done for different purposes. In the version ecoinvent data v 1.01 zinc coating and enamelling of steel and selective coating for solar collectors is addressed.

Many different welding techniques are industrially applied. Here two different techniques for welding steel and one for welding aluminium are assessed.

All the processing data have in common that they relate only to the actual processes. Thus e.g. coating of steel does not include the steel sheet to be coated. The same is true for forming and welding.

## 2 Steel forming

Authors: Silvio Blaser, Hans.Jörg Althaus, EMPA Dübendorf  
Review: Roland Hischier

### Acknowledgement

Thanks goes to Dr. Christoph Zeltner, from Stahl Gerlafingen AG in Gerlafingen, Switzerland, for the information about the consumed energy of the hot and cold rolling process and the wire drawing process; for the help in understanding the forming processes and the guided tour through the steel forming plant in Gerlafingen.

### 2.1 General remarks

The output of raw steel production are semi-finished products categorised in cast ingots, slabs, billets and beam blanks (for further details on their properties see (IPPC (2001a), page 11)). At this point of the production steps, the steel is relatively weak due to large and uneven metal crystals or grains. Rolling the semi-finished products causes the coarse grain structure to recrystallise into a much finer grain structure, giving greater toughness, shock resistance and tensile strength CRC (1998). Therefore in this study, as a first processing step, the raw steel output (see Part II, chapter 4.9 of this report) is hot rolled to different flat or long products.

After this first step, further forming processes like cold rolling, wire drawing, tubes drawing or section bar rolling can be applied. All those processes are described in this chapter/section.

### 2.2 Hot rolling of steel and chromium steel

The term "hot rolling" or "hot forming" is used when heat is applied to the workpiece before forming it between electrically powered rollers. In general, the temperature for hot forming is higher than the recrystallization temperature (temperature ranging from 1050 to 1300 °C). If the temperature is too high, a coarse-grained structure can be formed, which is undesirable (Kümmerling (1997)) and (IPPC (2001a)).

In contrast to further processing steps like for example cold rolling, for the hot rolling process steel and stainless steel are treated in approximately the same way. Therefore in this study, only one module and process description for those two materials was made.

The advantages of hot forming include (Kümmerling (1997)):

- Great formability of the workpiece,
- Small forces required, as the yield stress of the workpiece is low,
- Large degree of deformation possible in one forming step, with consequent reduction in processing time,
- Beneficial effect on the structure, and hence on the properties of the workpiece,
- Little or no work hardening (if this is not desired).

The most significant disadvantages of hot forming are:

- Very high cost of heating the workpiece compared with the energy required for forming,
- Capital investment for the heating furnaces,

- Very severe tool wear due to the very hard and brittle scale that forms on the surface of the work-piece,
- Reduced working life of the tools due to the thermal load and increased wear.

Typical in-going slabs are 400 to 2500 mm wide and 40 to 500 mm thick and can be rolled to a thickness of 1.2 to 20 mm by the hot rolling process. Products obtained from hot rolling are usually classified in two basic types according to their shape: flat and long products. In (IPPC (2001a)) production volume of hot rolled products is given: "Total EU production in 1996 of hot rolled (HR) products was 127.8 million tonnes of which flats accounted for 79.2 million tonnes (ca. 62%). Germany is the largest manufacturer of the flats, with 22.6 million tonnes followed by France with 10.7 million tonnes, Belgium 9.9 million tonnes, Italy 9.7 million tonnes and UK 8.6 million tonnes. The vast majority of HR flat products is wide strip. The remaining 38 % of HR products are long products with about 48.5 million tonnes in 1996. The two major manufacturing countries are Italy with about 11.5 million tonnes and Germany with 10.3 million tonnes; followed by UK (7 million tonnes) and Spain (6.8 million tonnes). The largest part of the long products sector in tonnage terms is the production of wire rod which stands for roughly a third of the total production followed by reinforcing bars and merchant bars with an approximate share of one quarter of the production each." Fig. 2.1 shows an overview of products manufactured for various purposes and applications.

Fig. 2.1 Overview of Hot Rolled Products (IPPC (2001a)).

Hot rolling usually comprise the following process steps (IPPC (2001a)):

- Conditioning of the input (scarfing, grinding),
- Heating to rolling temperature,
- Descaling,
- Rolling (roughing including width reduction, rolling to final dimension and properties),
- Finishing (trimming, slitting, cutting).

A short description of every single process step is given below in this chapter.

The infrastructure of a hot rolling mill comprises buildings where production processes take place and for storage, surroundings and machinery for the single process steps (e.g.: furnace, rolls, cutting devices, etc.) Infrastructure is described in detail in chapter 1.1.

### 2.2.1 Conditioning of the input (scarfing, grinding)

In IPPC (2001a) the surface conditioning process steps are described as follow:

"Slabs, blooms and billets can have surface defects, like cracks, folds or seams. Surface preparation of rolling stock is necessary to ensure flawless surfaces of the rolled product. Surface defects of semifinished products, can also be removed by the following processes.

#### Scarfig

Scarfig removes surface defects of carbon steel grades by an oxy-fuel flame. The flame is used to rapidly melt and oxidise the steel surface while a separate supply of high pressure oxygen to the cutter propels the slag product from the surface. (...)

The scale from machine scarfig is washed from the steel surface by high pressure water and led to a water pit where the scale is removed by crane. The water is treated and recirculated. (...)

Dust emissions from scarfig operation are collected and, usually, abated by electrostatic precipitators (wet or dry).

The consumption of fuel (natural gas, liquefied petroleum or plant gases) and oxygen for scarfig depends on the dimensions of the rolling stock. Variations of 20 % in consumption and emissions are possible when the e.g. thickness of a slab is increased from 200 mm to 250 mm.

#### Grinding

For stainless steels and special steel grades, thermal removal of the surface defects is not possible. Therefore defects have to be eliminated by grinding. (...) Grinding machines are equipped with a roller table on which the work piece is supported and on which it can be moved. The grinding wheel is mounted on a carriage that permits it to be moved back and forth over the work piece. The unit is positioned in an enclosure, which collects the dust generated during grinding and ducts it to a bag filter before discharge to atmosphere."

### 2.2.2 Heating to rolling temperature

Reheating is done in different types of furnaces such as pit furnaces, pusher type furnaces, walking beam furnaces, rotary hearth furnaces (which are the most usual type of continuous reheating furnaces) or others. For details of these furnace types consult (IPPC (2001a)) and (Brandt & Weiler (1997)). These furnaces are fired directly, usually by oil, natural gas or plant gases such as COG<sup>1</sup> and BFG<sup>2</sup>. Depending on the heating media, different waste gas emissions will occur (mainly SO<sub>2</sub> and NO<sub>x</sub>). Integrated steel plants try to valorise as much as possible the gases arising within the works for internal use. Hence blast furnace gas, coke oven gas, BOF gas, natural gas and a lot of different combinations of these gases (so-called mixed gases) are used in continuous furnaces IPPC (2001a). No data was available about the detailed consumptions of those gases, therefore in this study the whole energy consumption for the reheating process is inventoried as natural gas. Emissions resulting from burning the natural gas in the furnace, are not inventoried separately, because they are already included in the heat module used "natural gas, burned in industrial furnace low-NO<sub>x</sub> >100kW".

### 2.2.3 Descaling

Scale, which is formed during heating, must be removed prior to rolling in order to avoid a contamination of the stock surface by scale impressed by the rolls (so-called 'rolled in matter').

---

<sup>1</sup> COG: Coke oven gas

<sup>2</sup> BFG: Blast furnace gas

A common method of descaling is breaking and spraying off the scale by means of high-pressure water. Water with pressures of 120 to 250 bar (exceptionally 600 bar) is applied via flat jet nozzles onto the material surface (IPPC (2001a)).

The main wastes of descaling are iron oxides, oil free and oily scale and waste water.

#### **2.2.4 Rolling (roughing including width reduction, rolling to final dimension and properties)**

Hot rolling mills are classified by the type of product that they produce and by their design features. For a more detailed insight in the different mill layouts and manufacturing sequences, see (IPPC (2001a)), where information for blooming/slabbing mills, hot strip mills, plate mills, bar and rod mills, structural/section mills, tube mills are reported. In this study no differentiation for the various mill types are made.

Edging is usually applied in the manufacture of strip and plate for width reduction. Roughing depicts the first bulk reduction done on the incoming hot roll stock for the production of strip, rod and sections. Generally, the roughing train consists of one or more horizontal stands for thickness reduction, including edgers (vertical stands) situated in front of the stand for width adjustment (IPPC (2001a)).

Energy is used in form of electricity and the water consumption depends on whether the water flow design is an open, a semiclosed or a closed circuit. Dust and fugitive oil are emitted to the air.

#### **2.2.5 Finishing (trimming, slitting, cutting)**

In general, the finishing mill consists of a number of rolling stands positioned after one another. The stands have staggered roll gaps so that the thickness reduction to the requested final thickness is done in one pass of the transfer bar. Crop shears arranged in front of the finishing stands serve to cut the ends of the rough strip. Hot strips with length up to 2 km and even more are wound up on so named down (sometimes up-) coilers at the end of the rolling mill by speeds up to 20 m/s and more. The finishing train of rod mills usually consists of rolling blocks with up to 10 sets of alternating horizontal and vertical roller pairs (IPPC (2001a)).

#### **2.2.6 Environmental issues of hot rolling**

The main environmental issues of hot rolling are emissions to air, especially NO<sub>x</sub> and SO<sub>x</sub>; the energy consumption of furnaces; (fugitive) dust emissions from product handling, rolling or mechanical surface treatment; oil- and solid-containing effluents and oil-containing wastes (IPPC (2001a)).

Contaminated cooling and process water arising from processes of hot and cold forming of steel is treated in internal waste water treatment plants. The reference contained no data about the composition of the untreated wastewater but reported details about the pollutants composition of the purified water, when leaving the treatment plant (Tab. 2.1).

The purifying process generates 5 kg sludge per cubic meter of treated water, which is assumed to be disposed in a residual material landfill type with cement solidification. The composition of the arising sludge is not known and is therefore calculated / estimated by G. Doka (see also Doka (2003)). As no special heavy metal precipitating agents are used, the unknown sludge composition is derived proportionally to the pollutant profile in the purified wastewater (Tab. 2.1). The water content of the sludge is assumed to be 20%.

The values for the amount and composition of the treated wastewater are taken as proxy for the other steel forming processes.

**Tab. 2.1 Composition of purified waste water and of the arising sludge**

|                          | Amount in purified waste water | Amount in waste water treatment sludge |
|--------------------------|--------------------------------|----------------------------------------|
|                          | kg/m <sup>3</sup>              | kg/kg                                  |

### 2.2.7 Hot rolling in ecoinvent

Mean values are generally calculated as the geometric mean of the range given in IPPC (2001a). Where the range is given from zero to a maximal value, and the geometric mean can't therefore be calculated, the arithmetic mean is taken. The background information to the process "hot rolling, steel" is given in Tab. 2.2, flows are shown in Fig. 2.2.

#### Data quality

Data is taken almost exclusively from IPPC (2001a), some estimations are also made. The values can vary considerably depending on the degree of deformation.

Uncertainty is calculated assuming a lognormal distribution and the high value given in IPPC (2001a) representing the 95 % geometric standard deviation. Where no range is given in IPPC (2001a), the data quality is estimated by mean of the pedigree matrix, according to (Frischknecht et al. (2003)).

Tab. 2.2 Ecoinvent meta information for "hot rolling, steel"

| General Comment to reference function | To achieve greater toughness, shock resistance and tensile strength, the raw steel production outputs cast ingots, slabs, billets and beam blanks are hot rolled to long or flat products or semi-finished products. |

|                          |                              | Filter Dust to landfill | From 4.4% to 58.7 % of dust from air cleaning devices are landfilled. Given data represent few manufacturers, therefore 20 % of total dust from air cleaning device is assumed to be landfilled. The rest is assumed to be recycled and thus not inventoried. The proxy chosen to represent the dust stands for dust disposal from steelmaking, thus being quite accurate. | w aste management | residual material landfill | No              | CH       | disposal, dust, unalloyed EAF steel, 15.4% w ater, to residual material landfill | 4.42E-04   | kg                       | IPCC 2001             | 1    | 1.47               |                                                           |

Fig. 2.2 Flows for "hot rolling, steel" and their representation in the ecoinvent database (cont.)

## 2.3 Sheet rolling of steel

For many applications, the products of hot rolling are unsatisfactory, e.g., with respect to cross section, surface quality, dimensional accuracy, and general finish, so that cold rolling is necessary. Cold rolled products are mainly strips and sheets with high quality surface finish and precise metallurgical properties for use in high specification products.

In cold rolling, the properties of hot rolled strip products, e.g. thickness (typical final thickness from 0.1 to 3 mm), mechanical and technological characteristics, are changed by compression between rollers without previous heating of the input. However, its temperature can increase during the forming process, as the energy expended in forming is almost completely converted into heat. Frictional energy at the contact surfaces of the workpiece, if established, is also converted to heat. In rapid adiabatic processes the temperature can increase by  $>100\text{ }^{\circ}\text{C}$  (IPPC (2001a); Wiegels (1997)).

Contrarily to hot rolling, the process route of cold rolling is different for steel (carbon-or (low-)alloy steel) and for chromium steel (high alloy- or stainless steel). Therefore in this study those processes are described in two different chapters (see chapter 1.1 for chromium steel sheet).

The advantages of cold forming include (Wiegels (1997)):

For the workpiece:

- Good dimensional accuracy and close tolerances
- Good surface properties
- Very small dimensions (sheet thickness ca.  $10\text{ }\mu\text{m}$ , wire diameter ca.  $10\text{ }\mu\text{m}$ )
- Work hardening (if desired)

For the tool:

- Reduced wear (effective lubricants can be used, the thermal load is low, and scaling does not occur)

Generally:

- No energy is required for heating the workpiece

Cold rolled sheets and plates production (wide strip) was 39.6 millions tonnes in 1996. The main producing countries were Germany with 10.6 million tonnes followed by France with 6.3 million tonnes, Italy 4.3 million tonnes, UK 4.0 million tonnes and Belgium 3.9 million tonnes. Cold rolled narrow strip, obtained from cold rolling narrow hot strip or from slitting and cold rolling hot rolled sheet, amounted to about 8.3 millions tonnes in 1994 (2.7 million tonnes of cold rolled and 5.5 million tonnes of slit strip). In 1994, Germany produced about 35 % of the slit strip, with 1.9 million tonnes, followed by Italy and France each with a production of 0.9 million tonnes. (IPPC (2001a)).

The cold rolling mills for steel usually comprise the following process steps (IPPC (2001a)):

- Continuous pickling line,
- Cold rolling,
- Annealing,
- Temper mills,
- Inspection and finishing lines,
- Packaging lines for coils or sheets,

- Roll shop.

A short description of every single process step is given below.

The infrastructure of cold rolling mill for carbon steel is described in chapter 1.1. It comprises buildings where production processes take place and for storage, surroundings and machinery for the single process steps (e.g.: furnace, rolls, cutting devices, etc.).

### **2.3.1 Pickling**

The entire surface of the hot rolled coil is covered with a thin layer of scale containing oxides, which must be removed prior to cold rolling. Normal steels are usually pickled in sulfuric acid at 95–100 °C, or hydrochloric acid at 60–70 °C in three or four fully enclosed pickling baths. Before the actual pickling process, there is usually a stretcher–bend–leveling device which also causes mechanical descaling. This preliminary descaling is very important, as there must be a certain percentage of free iron surface in the pickling bath, so that pickling can start. Once the strip or sheet is pickled, it must be thoroughly rinsed with de-mineralised (or equal quality) water and subsequently dried. Oiling is done either with rolling oil or anticorrosive oil. The used acid can be regenerated, in the case of sulfuric acid by precipitating iron sulfate as its heptahydrate in a crystallizer. Hydrochloric acid can be regenerated by decomposing the iron chloride to hydrochloric acid and iron oxide, by a spray process at 450 °C, or in a fluidized bed at 850 °C (IPPC (2001a); Wiegels (1997))

### **2.3.2 Cold rolling**

The following description is taken from (IPPC (2001a); Wiegels (1997)). After pickling, the descaled hot-rolled strip is cold rolled passing through sets of rolls on reversing mills or on continuous in-line mills. Many types of stands are used in the production of cold-rolled strip, e.g., two-high, four-high, or larger.

Low carbon steels which are less hard, are generally rolled in multi-stand tandem mills due to a higher capacity of these mills. They consist of a series of four or six-high stands. The strip enters the first stand and undergoes an initial thickness reduction, further reductions are achieved in each subsequent stand until the final gauge is attained. For low carbon strip generally an emulsion of 0.5 to 4 % (10 - 20 % for direct application) of oil in water is necessary for lubrication, cooling of the strip, work and back-up rolls, and for removal of iron-particles. In the rolling process the wide strip is mainly deformed in a longitudinal direction, with transverse deformation being practically negligible. For optimum strip surface cleanliness it is important to avoid contamination of the tandem emulsion by the hydraulic oil, by grease or by the cooling water (used to cool the emulsion).

In reversing stands, one roll pass can be immediately followed by another by reversing the direction of the rollers. Reversing stands with many rolls exert a high pressure on the strip because the diameters of the working rolls are small.

Flat cold-rolled strip achieve thickness variations of only a few thousandths of a millimetre and a high-quality. Cold rolling causes work-hardening of the steel. This is reduced by an annealing stage.

### **2.3.3 Annealing**

The following chapter is taken from (IPPC (2001a))

The basic stages of the annealing process comprise:

- Heating to annealing temperature (above 650 °C),
- Holding at annealing temperature,

- Cooling.

This annealing process may be carried out in batch furnaces or continuous furnaces. The annealing cycle has a significant influence on the mechanical properties and, consequently, on the formability of the steel strip. The main parameter controlling the annealing cycle is the temperature profile.

Continuous annealing and batch annealing are considered to be complementary processes and not fully interchangeable. Production related issues are integral to the selection of the annealing technique.

### **Batch Annealing**

Prior to the annealing process the strip may be cleaned (degreased) to produce a cleaner surface. The most frequently used cleaning agents are phosphates, alkaline silicates, caustic soda and soda ash. The steel sheet is unwound from the coil and passed through cleaning tanks, which may be stirred to improve the cleaning effect. Subsequently, the steel is rinsed with water and recoiled. The degreasing solution can be regenerated and recycled.

The cold rolled coiled strip is stacked in a hood furnace for annealing. The combustion chamber (space between heating and protecting hood) is heated by oil or gas burners. Heat passes through the protective hood into where the steel coils are stacked. A circulating fan provides as uniform temperature distribution as possible. The atmosphere in conventional plants is usually HNX gas (a nitrogen-hydrogen mixture with a hydrogen content close to the flammability limit). The atmosphere can also be 100 % H<sub>2</sub> as in parts of the working cycle of high convection furnaces.

The heat passes into the coils through their outer edges, so that these areas are always hotter than the inner windings, especially during heating up. The heat treatment causes the organic residues of the emulsion to partly burn off; partly a distillation process takes place. Products of the reactions taking place are CO/CO<sub>2</sub>, H<sub>2</sub>, FeO<sub>x</sub> and CH<sub>4</sub>. The strip is heated to re-crystallisation temperature, and annealed at about 700 °C resulting in complete re-crystallisation of the cold rolled steel. For cooling the coils, the heating hood is removed. The cooling effect can be enhanced by spraying water on the protecting hood; by covering it with a cooling bell and blowing air on it or by using a cooling by-pass system which cools the protective atmosphere under the protective hood. The time necessary for annealing depends on the annealing temperature and the weight of the charge and can take 2 to 7 days. Annealing in this type of furnace is very slow and also the cooling rate is not suitable for certain steel grades. Therefore an annealing process in a 100 % hydrogen atmosphere was developed yielding in shorter annealing times and more rapid cooling.

### **Continuous Annealing**

For continuous annealing the coils are welded together on the entry side of the plant and subjected to the following process steps:

- Alkaline/electrolytic cleaning of the strips.
- Heating and holding at the required annealing temperature.
- Cooling (slow jet cooling, high gas jet cooling (using cooling rates up to 150 °C/s, hot water quench (HOWAQ), overaging, roll cooling, final cooling, misting jet cooling).

The continuous annealing is carried out by passing the steel strip through a multi-zone heating furnace with heating chamber, annealing chamber, cooling zone, tempering zone and a second cooling zone. The steel is heated to a range between 650 °C and 830 °C and then cooled by gas jets, gas-water sprays, contact rolls or water quenching, depending on the desired metallurgical properties. These furnaces are usually fired by gas (direct or indirect) or electrically heated. The steel can be protected by an inert gas atmosphere or a reducing gas atmosphere in parts of the furnace. Continuous annealing gives a shorter processing time (about 10 minutes), less intermediate storage, uniform mechanical properties and a superior surface cleanliness. Continuous annealing is more appropriate for the production of higher strength steels. The layout of the furnace facilitates energy recovery from the exhaust gas.

### 2.3.4 Tempering

After annealing the surface finish and mechanical properties of the steel are modified in line with the customer requirements. This is done by temper rolling which consists of subjecting the strip to a light rolling pass with a thickness reduction between 0.3 and 2 %. Before tempering the strip temperature must be less than 50 °C. Temper rolling is carried out in the temper mill which comprises typically one or two four-high stands, although two-high or six-high stands are also possible (IPPC (2001a)).

### 2.3.5 Inspecting and finishing

Finishing comprises slitting into coils of different width strip and transversal shearing to obtain sheet. Additional steps such as straightening, sampling, oiling and marking are also completed.

The finishing process comprises the following operations (IPPC (2001a)):

- Dimensional control (width, thickness and length),
- Inspection for surface defects and their removal,
- Sampling to determine the mechanical and technological properties, the strip roughness structure and the content of residue of particles from roll wear and carbon on the strip surface (statistical sampling),
- Trimming the coils to exact width,
- Straightening the strips to optimum flatness,
- Oiling the strips with electrostatic oiling machines or with oiling machines equipped with sprays or rolls oiling machines (anticorrosive oils or prelubes),
- Marking the finished products with coil number, production date, etc.
- Welding of different smaller coils to bigger coils.

### 2.3.6 Packaging of coils or sheets

The material, now in its final form, is usually packed ready for despatch to the customer. The packaging is designed to ensure that no damage occurs either during storage or transport to the end user. Control measures also have to be taken to prevent damage from mechanical and climatic sources. In addition the lifting and transport equipment in the production plant should also be designed and operated to minimize damage to the steel. After finishing, packing of the individual items ordered by the customers is done. The packing materials used includes: steel bands, paper, plastic, wood, seaworthy packing, special packing (IPPC (2001a)).

### 2.3.7 Maintenance of the rolls

The activities generally consist of the dismantling of the chocks, the grinding of the rolls, the texturing of the work rolls and the reassembling of the rolls. To satisfy the required strip tolerances and surface standards the rolls must be regularly reground. During this grinding operation the rolls are usually cooled and lubricated with a grinding emulsion. The spent emulsion can be recirculated and filtered, but partial replacement is required periodically. In addition, used oil and grinding sludge are produced which require disposal (IPPC (2001a)).

### **2.3.8 Environmental issues of sheet rolling of steel**

The main environmental issues of cold rolling are: acidic wastes and waste water; degreaser fume, acidic and oil mist emissions to air; oil-containing wastes and waste water (see chapter 2.2.6, Tab. 2.1); dust, e.g. from descaling and decoiling; NO<sub>x</sub> from mixed acid pickling and combustion gases from furnace firing. As for acid emissions to air from cold rolling, these may arise from pickling and acid regeneration processes. Emissions differ, depending on the pickling process used – basically the acid used. Only little data were available for dust emissions from steel handling and descaling operations (IPPC (2001a)).

### **2.3.9 Steel sheet rolling in ecoinvent**

Mean values are generally calculated as the geometric mean of the range given in IPPC (2001a). Where the range is given from zero to a maximal value, and the geometric mean can't therefore be calculated, the arithmetic mean is taken. The background information to the process "sheet rolling, steel" is given in Tab. 2.3, flows are shown in Fig. 2.3.

As no information on the shares of the different technologies for pickling, milling and annealing is available it is assumed that the respective shares are 50% each.

Water emissions with the treated wastewater are given in chapter 2.2.6, Tab. 2.1.

#### **Data quality**

Data is taken almost exclusively taken from IPPC (2001a), some estimations are also made. The values can vary considerably depending on the degree of deformation.

Uncertainty is calculated assuming a lognormal distribution and the high value given in IPPC (2001a) representing the 95% geometric standard deviation. Where no range is given in IPPC (2001a), the data quality is estimated by mean of the pedigree matrix, according to (Frischknecht et al. (2003)).

| Local Name                            | Blech walzen, Stahl                                                                                                                                                                                                                                                                                                                                                                                                                      |
| Synonyms                              | cold rolling                                                                                                                                                                                                                                                                                                                                                                                                                             |
| General Comment to reference function | This process is to be used only for un- and low-alloyed steel. For many applications, the products of hot rolling are unsatisfactory, e.g., with respect to cross section, surface quality, dimensional accuracy, and general finish, so that cold rolling is necessary. Cold rolled products are mainly strips and sheets with high quality surface finish and precise metallurgical properties for use in high specification products. |

| sheet rolling, steel, water and water treatment | mL           | Treated waste water    | One part of the incoming cooling and process water leaves the system as treated effluent; it is assumed to be discharged in surface water --> not inventoried. Infrastructure for waste water treatment plant is comprised in the infrastructure module for the whole rolling mill plant. Value for energy use is comprised in the broad range of uncertainty the energy data for the rolling mill have. |                  |                            |                 |          |                                                                               | 6.00E-03   | m <sup>3</sup>           | assumption            | 1    |                    |                  |

## 2.4 Sheet rolling of chromium steel

The process route for high alloy steel (stainless steel) requires an initial annealing step prior to pickling. This is necessary because, after the hot rolling process, the strip cools slowly, and carbon tends to precipitate at the grain boundaries, owing to its reduced solubility at lower temperature. Annealing causes the carbon to go back into solution. Rapid cooling of the strip then prevents the carbon from precipitation by diffusion. Further more, several additional annealing and/or pickling steps during rolling may be necessary.

Due to the different material characteristics, the field of application of chromium steel is very different from the one of steel. The production volume of chromium steel is much smaller (estimated 5 %) than the one of carbon and low alloyed steel<sup>3</sup>.

The cold rolling mills for chromium steel usually comprise the following process steps (based on IPPC (2001a)):

- Annealing (I) and pickling (I) of chromium steel,
- Cold rolling,
- Annealing (II) and pickling (II) of chromium steel,
- Tempering,
- Inspecting and finishing,
- Packing coils or sheets,
- Roll maintenance.

A short description of the process steps which differs from the steel sheet rolling (annealing and pickling I & II and cold rolling) is given below. For the other process steps see chapter 2.3.

The infrastructure of cold rolling mill for stainless steel is described in chapter 1.1. It comprises buildings where production processes take place and for storage, surroundings and machinery for the single process steps (e.g.: furnace, rolls, cutting devices, etc.).

### 2.4.1 Annealing (I) and pickling (I) of chromium steel

The process of first annealing and pickling of chromium steel is described in (IPPC (2001a)).

Due to the presence of an oxide scale and chromium depleted layer formed during the hot rolling the steel must also be descaled / pickled prior to cold rolling. In addition, the greater hardness of the steel compared with carbon steels necessitates an initial annealing (I). The annealing process has three components, heating to annealing temperature, temperature equalisation and cooling. Both continuous and batch annealing processes may be used.

Ferritic grades are generally annealed as tightly wound coils in a batch heat treatment facility. Heating may be achieved via gas firing or electrical heating. An inert protective atmosphere (nitrogen/hydrogen) is required for metallurgical reasons. Ferritic steels are generally annealed at steel temperatures of up to 800 °C.

For continuous annealing of austenitic steels the steel coil is unwound and passed through one or more heat treatment furnaces. An oxidizing atmosphere is needed to form a scale, which is rich in oxygen to allow a better pickling. The waste gases are exhausted via flues under natural or forced draft. Strip temperatures typically up to 1100 °C are necessary for annealing austenitic steels. The steel strip then

---

<sup>3</sup> Personal communication on 25. February 03 from Dr. Ch. Zeltner, Stahl Gerlafingen, Swiss Steel Ltd.

passes through the cooling section and may be cooled using gas jets, air, water sprays or water quenching. Continuous annealing is generally combined with a descaling/pickling plant to form a continuous annealing and pickling line.

After annealing the steel is descaled to produce a steel surface suitable for cold rolling. Mechanical descaling such as shot blasting or scale breaking may be used prior to chemical pickling to remove the heavy scale burden. However, careful control of such mechanical processes is necessary to minimise damage to the strip surface, which could affect the final product quality. Final scale removal including the removal of the chromium depleted layer beneath the scale is generally done by pickling in a mixture of nitric and hydrofluoric acids at temperatures of up to 70 °C.

The chemical reactions that take place during the pickling of stainless steels are complex and involve the removal of the adherent scale layer by the combined action of the acids used. For further details consult directly the source (IPPC (2001a)).

Pickling line design is usually the same as for pickling of low alloy steels. Except, that on exit from the last pickling tank the steel strip is rinsed with water to remove traces of acid, dried, but no application of oil is necessary because of the corrosion resistance of the steel.

### **2.4.2 Cold rolling**

The cold rolling mill is described in (IPPC (2001a)) as follows:

After the initial annealing and pickling the steel is generally rolled to the required thickness on reversing cluster mills for a number of passes until the desired dimensions are achieved or until work hardening necessitates further annealing. Reversing stands with many rolls exert a high pressure on the strip because the diameters of the working rolls are small. These stands are therefore mainly used for steels with work-hardening properties, e.g., stainless steels and electric sheet steels.

The process of cold reduction generates heat, part of which is transferred to the rolling oil which is sprayed onto the steel and rolls for cooling as well as lubrication. This heat is subsequently dissipated through heat exchangers to cooling water systems.

Mineral oils are generally used as rolling oil and close control of the oil cleanliness is necessary for optimum performance. This may be achieved using oil filtration circuits, which incorporate media element filters or powder pre-coat filter systems. Although the use of mineral oils predominates, emulsion cooling systems similar to those used for carbon steels may be employed. In such cases additional precautions must be taken to control oil cleanliness in order to avoid strip marking. Collection hoods are fitted to the mill and operate under continuous extraction to remove oil mist that is generated.

### **2.4.3 Annealing (II) and pickling (II) of chromium steel**

Annealing and pickling are described in (IPPC (2001a); Wiegels (1997)).

Prior to the final annealing process, degreasing of the strip may be required to remove any contaminants from the steel surface. This can be achieved using an alkali based cleaning systems, which may be incorporated in the entry section of continuous annealing lines. The steel coil is unwound and passed through a series of tanks containing the cleaning solutions. Agitation of the solution is usually incorporated to enhance the cleaning. Afterwards the strip is rinsed with water. De-mineralised water can be used for the final rinsing step.

The process route for final annealing and pickling is dictated by the surface finish required. Examples of this are EN standard finish '2R' which requires a bright annealing treatment and surface finish '2B' which requires annealing and pickling.

Bright annealing is generally conducted in an electrically heated or gas fired furnace with a protective inert atmosphere of nitrogen and/or hydrogen. Both batch annealing and continuous annealing may be used. Degreasing of the steel surface is required to prevent surface discolouration.

Material with a '2B' surface finish is generally processed on continuous annealing and pickling lines. The furnace design and operation is generally similar to that for the annealing of hot band material described above. The steel is unwound and passed through one or more furnaces, which are usually gas fired. Annealing takes place in an oxygen rich atmosphere. This is necessary to ensure that the scale generated in the furnace is of a composition that is readily removable by the downstream chemical pickling processes. Stainless steels are to an increasing extent being annealed in bright annealing plants, as this process enables the bright surface produced by cold rolling, and typical of special steels, to be retained.

Unlike the descaling of hot band material described above, mechanical descaling techniques cannot be employed to assist in the removal of this scale due to the surface damage which would result for the final cold rolled strip. Therefore only chemical pickling is applied. This is done in the same manner as described above for hot band pickling. Scale of high alloy steel, due to the presence of oxides of alloying elements, cannot always be removed in just a single acid descaling step. Additional treatment or pre-treatment processes may be necessary. These may include scale removal by an initial electrolytic descaling process (using e.g. sodium sulfate) installed prior to the mixed acid section.

#### **2.4.4 Environmental issues of sheet rolling of chromium steel**

Unlike sulfuric acid or hydrochloric acid pickling solutions, regeneration is not possible, so that the spent acids must be rendered harmless and disposed off (Wiegels (1997)). For other environmental issues, see chapter 2.3.8.

#### **2.4.5 Chromium steel sheet rolling in ecoinvent**

Mean values are generally calculated as the geometric mean of the range given in IPPC (2001a). Where the range is given from zero to a maximal value, and the geometric mean can't therefore be calculated, the arithmetic mean is taken. The background information to the process "sheet rolling, chromium steel" is given in Tab. 2.4, flows are shown in Fig. 2.4.

Water emissions with the treated wastewater are given in chapter 2.2.6, Tab. 2.1.

#### **Data quality**

Data is almost exclusively taken from IPPC (2001a), some estimations are also made. The values can vary considerably depending on the degree of deformation.

Uncertainty is calculated assuming a lognormal distribution and the high value given in IPPC (2001a) representing the 95 % geometric standard deviation. Where no range is given in IPPC (2001a), the data quality is estimated by mean of the pedigree matrix, according to (Frischknecht et al. (2003)).

| General Comment to reference function | This process is to be used only for high alloyed (chromium) steel. For many applications, the products of hot rolling are unsatisfactory, e.g., with respect to cross section, surface quality, dimensional accuracy, and general finish, so that cold rolling is necessary. Cold rolled products are mainly strips and sheets with high quality surface finish and precise metallurgical properties for use in high specification products. |

Infrastructure for waste water treatment plant is comprised in the infrastructure module for the whole rolling mill plant. Value for energy use is comprised in the broad range of uncertainty the energy data for the rolling mill have. |                        |                            |                 |          |                                                                               | 5.25E-03   | m <sup>3</sup>           | IPCC 2001             |      |                    |                                                           |

## 2.5 Wire drawing of steel and chromium steel

Wire drawing is a process in which wire rods/wires are reduced in size by drawing them through cone-shaped openings of a smaller cross section, so called dies. The input usually is wire rod of diameters ranging from 5.5 to 16 mm obtained from hot rolling mills in form of coils.

The European Union has the world largest wire drawing industry, followed by Japan and North America. It produces about 6 million tonnes of wire per year. Including the various wire products, such as barbed wire, grill, fencing, netting, nails etc, the production of the sector reaches more than 7 million tonnes per year. The largest producer of steel wire is Germany with 32 % (about 1.09 million tonnes) of EU wire production, followed by Italy (approx. 22 %, 1.2 million tonnes), UK, Benelux (mainly Belgium), France and Spain.

A typical wire drawing process line comprises the following steps (IPPC (2001a)):

- Pre-treatment of the wire rod (mechanical descaling, pickling).
- Dry or wet drawing (usually several drafts with decreasing die sizes).
- In some cases heat treatment (continuous-/discontinuous annealing, patenting, oil hardening).
- Finishing.

The final diameter size of dry drawn wire is between one and two millimetres, wet drawn wire has an even smaller diameter. A short description of every single process step is given below.

Wire is manufactured in different grades of steel: low carbon steel with carbon content of up to 0.25 %, high carbon steel with a carbon content of over 0.25 %, stainless and other alloy steel. Non-alloy steel wire can be uncoated or coated with zinc, copper, brass, tin, nickel, chrome, plastic or varnish. Wire is sent as coils to further processing, like coating and manufacturing of finished products (e.g. cable, mesh, barbed wire, wire fencing, grill, springs, nails).

The infrastructure of steel and chromium steel wire drawing is described in 1.1. It comprises buildings where production processes take place and for storage, surroundings and machinery for the single process steps (e.g.: furnace, rolls, cutting devices, etc.).

### 2.5.1 Pre-treatment of the wire rod

Pre-treatment of wire rod is described in (IPPC (2001a)).

"Air-cooling after rolling produces an iron oxide-layer (scale) on the wire rod surface. This layer is very hard, brittle and not deformable and must therefore be removed before any further processing can take place. Two techniques for descaling wire rods are applied: mechanical descaling and chemical pickling.

#### **Mechanical descaling of wire rod**

In the most common mechanical descaling method applied: wire bending, the wire is bent to cause the brittle scale to peel off. Other descaling techniques, like sanding, brushing or shot blasting, are used as a finishing step after wire bending to remove loose scale or are used as stand-alone techniques. Wire bending, generates a relatively coarse scale, which generates only negligible amounts of dust.

#### **Chemical descaling (pickling) of wire rod**

In chemical descaling the mill scale is removed by dissolving in acid. Acids used are:

- Sulphuric or hydrochloric acid for low carbon wire.
- Hydrochloric acid for high carbon wire.

Pickling is mostly done in a batch process. Each roll of wire rod is immersed in the acid bath. The acid slowly dissolves the oxide layer by transforming it into iron chlorides or sulphates. When pickling in HCl an  $H_2$ -inhibitor is used to suppress the reaction:  $2\text{HCl} + \text{Fe} \rightarrow \text{FeCl}_2 + H_2$  and reduce the unwanted loss of iron. After pickling the wire rod coils are rinsed in water. This is usually done in cascade rinsing (e.g. rinsing 3 times) to yield maximum rinsing efficiency and minimum water consumption.

### **Application of Soap (Lubricant) Carrier**

In some cases, soap carrier is applied to enhance the adhesion of the lubricant to the wire. A wide range of soap carriers is available. Selection is made on economical basis and on required properties in downstream processes. Traditional soap carriers include lime, borax and Zn-phosphate. Modern soap carriers are typically mixtures of soluble salts, e.g. sodium and potassium sulphate, chloride, borax, phosphate or silicate. They are adapted to a particular soap and a particular drawing situation. Soap carrier is applied before drawing by dipping the wire in a watery soap carrier solution. This can be done in a batch process, usually associated with chemical descaling, or continuous in association with mechanical descaling.

Consumption and emissions associated with the application of soap carrier vary in dependence of the type of soap carrier, thickness applied and the wire rod diameter. No quantitative data is available at the moment.

If  $\text{Zn-PO}_4$  coating is used, a thick  $\text{FePO}_4$  sludge or cake is formed containing traces of zinc, soluble phosphates and chlorate or nitrite coming from the  $\text{Zn-PO}_4$  bath. Also spent soap carrier bath may arise as liquid waste. If drying is done in gas - or fuel fired ovens, the usual combustion products are emitted."

### **2.5.2 Dry drawing of wire**

Dry drawing is typically used to draw wire rod ( $> 5.5\text{ mm}$ ) to a product diameter of 1 - 2 mm. The diameter of wire is reduced by passing it through a series of dies with diminishing diameter. Before entering the dies, the wire is passed through a dry lubricant. In most cases, soap-based lubricants are used with the soap formulation depending on choice of fats from which the soap is produced, choice of fillers or choice of additives. In exceptional cases (e.g. special steels, wire with special metal coatings) other lubricants like pastes or oils can be used. The drawing operation heats both (wire and drawing die) through friction of the wire. Cooling is done indirectly, by cooling the capstans in contact with the wire with water (IPPC (2001a)).

### **2.5.3 Wet drawing of wire**

Wet drawing is typically used to draw wire with an intermediate product diameter of 1 - 2 mm to final diameter. The wire is also passed through a series of dies with diminishing diameter, but wire, dies and capstans are immersed in a lubricant liquid that provides lubrication and cooling. Typically, soap or oil emulsions (for some applications plain oil) are used. The heat resulting from drawing operation is taken up by the lubricant, which is cooled indirectly with water (IPPC (2001a)).

### **2.5.4 Heat treatment of wire**

Heat treatment of wire has different goals. Therefore different types of heat treatment are applied depending on the type of steel (low carbon / high carbon / stainless) and the final use (desired ductility and strength). Heat treatment also removes soap and lubricant residues thermally. The following heat treatment types are applied (IPPC (2001a)):

- Batch annealing,
- Continuous (In-Line) annealing,
- Patenting,
- Oil hardening and tempering,
- Stress-relieving.

A considerable percentage of the output of the wire industry does not need any heat-treatment. The heavy deformation of the metal crystal structure caused by drawing increases the hardness and the strength of the wire in the axial direction (IPPC (2001a)).

### **Batch annealing**

Drawing profoundly deforms the shape of the metal crystals of the wire. Annealing is one of the different methods to re-obtain a suited crystal shape. Batch annealing, typically used for low carbon steel wire to obtain a very soft and ductile end product, is done in bell or pot furnaces, in chambers filled with a either neutral or reducing protective gas (nitrogen, hydrogen, nitrogen/hydrogen mixtures and partly oxidized natural gas) and typically heated by gas or fuel. The warming up from room to peak temperature (roughly 700 °C) takes several hours; also cooling down again takes several hours. In order to keep an over-pressure in the "pots" or "bells", a fraction of the protective gas is continuously purged. In some cases, the wire is oiled immediately after annealing (IPPC (2001a)).

### **Continuous (In-Line) annealing**

Continuous annealing or strand-annealing has a similar goal as batch annealing: restore a suited crystal texture to the steel in the wire after drawing. But the desired crystal shape and metal properties are different from those that are desired when batch-annealing is applied. Continuous annealing is a typical heat treatment method for low carbon products. Strand-annealing is a fast continuous process. The wire is heated up to the recrystallisation temperature (500 - 700 °C) commonly by passing through a molten lead bath, is kept at this temperature for a few seconds, and is cooled down again by quenching in a water bath. This can be followed by in-line pickling with warm or cold HCl, other acids or electrolytes, to remove oxides which also partly dissolves the potentially dragged lead. Pickling is followed by a rinsing cascade (IPPC (2001a)).

For stainless steel, the heat-treatment is done under a protective gas atmosphere as if no protective atmosphere would be used, the stainless steel wire would be oxidized; removal of these oxides would require pickling with special acids. The heating can be done by electricity (resistance heating, inductive heating) or by combustion (IPPC (2001a)).

### **Patenting**

Patenting is a heat-treatment method typically used for high-carbon and alloyed steel products to create a special crystal structure, which allows easy further deformation. In contrast to annealing where iron and iron/carbon compounds tend to be separated, patenting yields a structure where the carbon is homogeneously distributed in the iron. Patenting is done by heating the wire to 850 - 1000 °C, then cooling fast to 450 - 600 °C and keeping the wire for a while at this temperature, and finally quenching in water (IPPC (2001a)).

### **Oil hardening and tempering**

Oil hardening and tempering creates a special crystal structure in the steel with a high percentage of martensite, resulting in increased hardness and wear resistance combined with good toughness. First, the wire is heated to 850 – 1000 °C, followed by rapid cooling. Oil-hardening is always followed by a tempering or stress-relieving step, in order to remove the stresses caused by the extremely fast cooling. This is done by heating the wire again to 300 – 500 °C. Typically a normal oven is used, with electrical heating or direct heating with a typical combustion gas, but also inductive heating can be used (IPPC (2001a)).

### **Stress-relieving**

The goal of stress-relieving is to remove internal stresses in the wire caused by a previous processing steps, without changing the shape and structure of the steel crystal. The internal stresses can be caused by deformation (mechanical stresses) or by fast cooling (thermal stresses). Stress-relieving as a stand-alone heat-treatment step is a typical process step for the production of PC-strand (wire for prestressed concrete). Stress-relieving can be done at various temperatures (200 - 500 °C), dependent on the desired characteristics of the final product. Typically a normal oven is used, with electrical heating or direct heating with a typical combustion gas, but also inductive heating can be used. After stress-relieving, the wire is cooled relatively slowly in air or water (IPPC (2001a)).

## **2.5.5 Environmental issues of wire drawing of steel**

The main environmental aspects of wire drawing are: air emissions from pickling, acidic wastes and waste water; fugitive soap dust (dry drawing), spent lubricant and effluents (wet drawing), combustion gas from furnaces and emissions and lead-containing wastes from lead baths (IPPC (2001a)).

## **2.5.6 Wire drawing of steel and chromium steel in ecoinvent**

For mechanical wire rod preparation, only data about wire bending were available. No data were available about the application of soap carrier, for batch annealing, for oil hardening and tempering, annealing of stainless steel wire and stress relieving. For the heat treatment available data were inventoried only with 25 %, because 75 % of drawn steel underlies no further tempering.

The output is wire drawing for 1 kg of product. If coated wire is needed, one has to apply an additional module, e.g. "zinc coating, coils" or "zinc coating, pieces".

Mean values are generally calculated as the geometric mean of the range given in IPPC (2001a). Where the range is given from zero to a maximal value, and the geometric mean can't therefore be calculated, the arithmetic mean is taken. The background information to the process "wire drawing, steel" is given in Tab. 2.5, flows are shown in Fig. 2.5.

Wastewater is estimated based on the wastewater from hot and cold rolling.

### **Data quality**

Data is taken almost exclusively taken from IPPC (2001a), some estimations are also made. The values can vary considerably depending on the degree of deformation.

Uncertainty is calculated assuming a lognormal distribution and the high value given in IPPC (2001a) representing the 95 % geometric standard deviation. Where no range is given in IPPC (2001a), the data quality is estimated by mean of the pedigree matrix, according to (Frischknecht et al. (2003)).

| General Comment to reference function | Wire drawing is a process in which wire rods/wires are reduced in diameter by drawing them through cone-shaped openings of a smaller cross section, so called dies. The input usually is wire rod of diameters ranging from 5.5 to 16 mm obtained from hot rolling mills in form of coils. The final diameter size of dry drawn wire is between one and two millimetres, wet drawn wire has an even smaller diameter. |

Doka). Assumption: waste water treatment is comparable with the WWT of hot and cold rolling                                                                                                                                                                                                                                                 | chemicals              | inorganics                                               | No               | GLO                        | chemicals inorganic, at plant   | 1.84E-08   | kg                                                                            | IPCC 2001                | 1    | 1.31               | (2,5,1,1,3,3,4)  |      |                  |
|                                   |                                                  |                                                                                                                                                                                                                                                                                                                                                  | One part of the incoming cooling and process water leaves the system as treated effluent; it is assumed to be discharged in surface water --> not inventoried. Infrastructure for waste water treatment plant is comprised in the infrastructure module for the whole rolling mill plant. Value for energy use is comprised in the broad range of uncertainty the energy data for the rolling mill have. |                        |                                                          |                  |                            |                                 | 7.00E-03   | m3                                                                            | IPCC 2001                |      |                    |                  |      |                  |

## 2.6 Pipe drawing of steel and chromium steel

The production process and volume of drawn pipes (or seamless tubes) is described in (IPPC (2001a)).

Steel tubes cover three product categories, which differ considerably in manufacturing process, raw materials, and investment requirements. These categories are classified as:

- Seamless tubes.
- Welded steel tubes of circular cross-section over 406.4 mm in outside diameter.
- Welded steel tubes of circular cross-section up to and including 406.4 mm in outside diameter together with welded steel tubes of non-circular cross-section of any perimeter.

In steel tube manufacture, the EU, which produced 11.8 million tonnes in 1996, (20.9 % of total world production) is the largest producer followed by Japan and the U.S. The European steel tube industry has a highly concentrated structure. Five countries – Germany (3.2 million tonnes), Italy (3.2 million tonnes), France (1.4 million tonnes), United Kingdom (1.3 million tonnes) and Spain (0.9 million tonnes) - account for roughly 90 % of total EU production. About 26.4 % of the tubes produced are seamless tubes, of the remaining 73.6 % welded tubes about 18.9 % are of large diameter. The major part of the total steel tube sector is small diameter tubes with a share of 54.7 %.

Nevertheless this type of pipes represent only about one quarter of total production, in this study the focus was laid on the manufacturing of seamless pipes. The reason is that, if LCI data is needed about welded tubes, they can be gained easily, combining different ecoinvent modules. In fact welded tubes are produced from cold rolled or hot rolled steel strip; hot rolled wide strip; or thick plate. In principal the production sequence comprises bending of the strip or plate to an open tube and closing the gap by welding. Therefore ecoinvent modules of steel, of steel sheet production and welding are needed.

Seamless tube production consists basically of the following manufacturing steps:

- Heating of the input.
- Piercing (press-piercing or oblique rolling).
- Elongation/Stretching.
- Final Rolling.
- Heat Treatment.

The most important types of plants used today are mandrel mills, plug mills, push bench mills and pilger mills. Raw material for the production of unalloyed and medium-alloy steel tubes are continuously cast round billets or blooms, the raw material for high-chrome steel tubes are mainly round bars, rolled from cast billets.

The input is heated to rolling temperature in rotary hearth furnaces fired with natural gas or oil. Then a hollow billet (ingot) is produced by piercing. The most important hole-piercing process uses inclined rollers. Longitudinal rolling, transverse rolling, or presses are used for the elongating stage. The most important one is the continuous tube rolling process, as it is one of the most efficient and productive processes.

Tubes for undemanding applications can be shipped immediately after rolling. For more exacting quality requirements, especially good toughness properties, separate heat treatment is usually carried out after rolling. This can include normalising and tempering.

The infrastructure of steel and chromium steel pipes drawing is described in 1.1. It comprises buildings where production processes take place and for storage, surroundings and machinery for the single process steps (e.g.: furnace, rolls, cutting devices, etc.).

### **2.6.1 Pipe drawing of steel and chromium steel in ecoinvent**

No data was available about the production process of seamless pipes. As an approximation it was decided to compare the tube production process with one of the forming processes for steel and chromium steel, described above, for which data was available. The wire drawing process was evaluated being the one that describes the pipes drawing process the best. As the geometry of the pipe is more complex as the geometry of the wire, pipe drawing is inventoried with 110% of wire drawing.

The background information to the process "drawing of pipes, steel" is given in Tab. 2.6, flows are shown in Fig. 2.6.

#### **Data quality**

Uncertainty is estimated by mean of the pedigree matrix, according to (Frischknecht et al. (2003)).

## **2.7 Section bar rolling of steel**

The production process of section bar rolling is not described in details in the studied literature and no data about material and energy flows were available. An extract of the description found in (IPPC (2001a)) is reported below.

As most other types of mills, section rolling mills are divided into roughing, intermediate and finishing stands, preceded by a descaling machine installed between the reheating furnace and the roughing mill. On leaving the finishing stand or train, the bars are divided to cooling bed length or to commercial length by saws. After cooling on the cooling bed, the bars are straightened on mechanical or hydraulic straightening machines and cut to length by saws as required.

As conclusion from this description and the lack of data, it was decided to combine other ecoinvent modules to reach an approximation of the relevant flows of the section bar rolling process.

The infrastructure of steel section bar rolling is described in 1.1. It comprises buildings where production processes take place and for storage, surroundings and machinery fore the single process steps (e.g.: furnace, rolls, cutting devices, etc.).

### **2.7.1 Section bar rolling of steel in ecoinvent**

Due to the lack of data, the section bar rolling process is approximated by inventorying 10% of the wire drawing process.

The background information to the process "section bar rolling, steel" is given in Tab. 2.6, flows are shown in Fig. 2.7.

#### **Data quality**

Uncertainty is estimated by mean of the pedigree matrix, according to (Frischknecht et al. (2003)).

| General Comment to reference function | Seamless tube production consists basically of the following manufacturing steps: Heating of the input, Piercing (press-piercing or oblique rolling), Elongation/Stretching, Final Rolling and Heat Treatment.      | As most other types of mills, section rolling mills are divided into roughing, intermediate and finishing stands, preceded by a descaling machine installed between the reheating furnace and the roughing mill. After cooling on the cooling bed, the bars are straightened on mechanical or hydraulic straightening machines and cut to length by saws as required |

| Technology text                       | Average technique for EU. Because of the lack of data about the production process, it was approximated with the production process of steel wire drawing.                                                          | Average technique for EU. Because of the lack of data about the production process, it was approximated with the production process of wire drawing.                                                                                                                                                                                                                 |

## **2.8 Infrastructure of the rolling mill**

### **2.8.1 Land use and buildings of the rolling mill**

Data on land use of rolling mills are based on the map of the steel producing and forming plant of Stahl Gerlafingen, an enterprise of the Swiss Steel Ltd.

The total area of the plant was read from a map with the scale of 1:6000. The buildings were estimated covering 25 % of the total area of the plant, 75 % are therefore surroundings, which are further distinguished in 5 % green area and 95 % built up or asphalted surface.

The area of the buildings belonging to the steel manufacturing part of the plant could be read from the map<sup>4</sup>, they were estimated to be occupying 20 % of the total build-up surface of the plant. Therefore the total area, the surroundings and the built-up area belonging to the rolling mill amount to 80 % of the total area of the plant. Only the surface of the administration buildings was divided into equal parts (4000 m<sup>2</sup>) for the steel manufacturing and the steel rolling process. The total area of the rolling mill is 310'000 square meters, all other values were calculated basing on this value. The buildings were estimated to be 10 m high and to have a lifetime of 50 years.

### **2.8.2 Machinery and disposal of the machinery of the rolling mill**

Absolutely no data about the amount of machinery was available, therefore it was necessary to make a rough estimation of the volume, respectively the volume of the main components of the machinery. It is assumed that the machinery is basically composed of steel on a foundation of concrete. The volume of the machinery was estimated to be 0.5 % of the buildings volume of the rolling process. The concrete fundament is assumed to have the same mass as the machines. Density of the steel is 7850 kg/m<sup>3</sup>, that of the concrete 2300 kg/m<sup>3</sup>. The lifetime of the machinery was estimated to be 25 years.

The yearly output of the visited plant amounts to 616000 tonnes of formed steel.

The module for concrete disposal from building includes recycling and disposal and it is assumed that 100 % of the steel is recycled.

### **2.8.3 Infrastructure of the rolling mill in ecoinvent**

The background information to the process "rolling mill" is given in Tab. 2.7, flows are shown in Fig. 2.8.

#### **Data quality**

Uncertainty is estimated by mean of the pedigree matrix, according to (Frischknecht et al. (2003)).

---

| General Comment to reference function | The values for plant area were taken from a map received during the visit to a electro-steel manufacturing and forming plant in Gerlafingen, Switzerland. The output was 616000 tonnes of formed steel in 2002. The Lifetime is assumed to be 50 years for infrastructure like buildings and routes, and 25 years for machinery and furnaces |

## 3 Aluminium forming

Authors: Silvio Blaser, Hans.Jörg Althaus, EMPA Dübendorf  
 Review: Roland Hischier

As for steel, the outputs of the aluminium production are slabs with relatively coarse shape, which can be further formed to sheets, foils or section bars.

### 3.1 Sheet rolling of aluminium

The proceedings of rolling aluminium from an initial rough form to a well defined sheet is similar to the processes taking place in steel forming, therefore it is not described in every detail.

An overview of the different process steps taking place, when Aluminium is rolled to sheet form, is given in Fig. 3.1.

The basic input material for sheet fabrication is primary or secondary aluminium ingot of 500 to 700 mm thickness and a weight up to 25 tonnes. After heating the aluminium slab to around 500 °C, it is hot rolled, typically to 2-8 mm thickness, followed by cold rolling to the final gauge, 0.2 to 6 mm (EAA (2000)).

As the process steps are similar to those of steel forming, also the infrastructure needed to roll aluminium slabs into sheet form, is assumed to be similar. It is balanced the same amount of rolling mill per volume unit of rolled material, as it is for the forming processes of steel.

#### 3.1.1 Environmental issues of sheet rolling of aluminium

In the data referred in the considered literature (EAA (2000)), the main air and water emissions, are arising from the combustion of energy carriers. Emissions to land are mainly hazardous and oily wastes.

#### 3.1.2 Sheet rolling of aluminium in ecoinvent

The inventory data reported were obtained from an industry-wide survey carried out in 1998. For the sheet rolling industry segment, the survey coverage was 71% related to the total production output (EAA (2000)).

The basic input material, primary aluminium is not balanced. The scrap losses of aluminium are mainly internally recycled, this recycling process is not balanced. A small amount of scrap material is not recycled, but is lost in waste. To obtain an even mass balance for 1 kilogram of output product, it is necessary to balance the 12 grams lost in waste as input of primary aluminium (Fig. 3.1).

The background information to the process "sheet rolling, aluminium" is given in Tab. 3.1, flows are shown in Fig. 3.1

#### Data quality

A standard precision of 5% percent of the value is given in EAA (2000)(), to obtain a more detailed view of the data quality, the uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)).

Fig. 3.1 Aluminium sheet rolling process; values are aluminium flows (modified from EAA (2000))

| Data Set Version                      | 1                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| Included Processes                    | All the process steps, which can be attributed to semi-fabrication (sawing, scalping, hot rolling, cold rolling, solution heat treatment, finishing and packaging), are included. Does not include the material being rolled, only the amount of scrap lost in waste is balanced as primary aluminium input. Includes the transport of the materials to the plant, but does not include the transport of the product to the customer. |
| Amount                                | 1                                                                                                                                                                                                                                                                                                                                                                                                                                     |

| General Comment to reference function | Aluminium ingots of 500-700 mm thickness and up to 25 tonnes are rolled, first hot, then cold, to a final sheet thickness ranging from 0.2 to 6 mm. The module can be applied also for section bar rolling of aluminium.                                                                                                                                                                                                              |

## 3.2 Section bar extrusion of aluminium

"Extrusion is the process of forcing heated aluminium through a die under extreme force to produce the desired shape. Extrusions can be made in literally thousands of complex shapes. Billets are pre-heated and forced by a ram through one or more dies to achieve the desired cross-section. The product is long in relation to its cross-sectional dimensions and has a cross section other than that of rod and bar and pipe and tube"<sup>5</sup>. The starting material for aluminium extrusion production is an extrusion billet (or extrusion ingot), coming from either primary or secondary aluminium production.

An overview of the different process steps taking place, when Aluminium is extruded to a profile, is given in Fig. 3.3.

The same amount of rolling mill infrastructure balanced per volume unit of treated material for the steel forming processes, is inventoried for the section bar extrusion of aluminium.

### 3.2.1 Environmental issues of section bar extruding of aluminium

In the data referred in the considered literature (EAA (2000)), the main air and water emissions, are arising from the combustion of energy carriers. Emissions to land are mainly hazardous and oily wastes.

### 3.2.2 Section bar extruding of aluminium in ecoinvent

The inventory data reported were obtained from an industry-wide survey carried out in 1998. For the section bar extruding industry segment, the survey coverage was 30 % related to the total production output (EAA (2000)).

The basic input material, primary aluminium is not balanced. The scrap losses of aluminium are mainly internally recycled, this recycling process is not balanced. A small amount of scrap material is not recycled, but is lost in waste. To obtain an even mass balance for 1 kilogram of output product, it is necessary to balance the 13 grams lost in waste as input of primary aluminium (Fig. 3.3).

The background information to the process "section bar extrusion, aluminium" is given in Tab. 3.2, flows are shown in Fig. 3.2.

#### Data quality

A standard precision of 5% percent of the value is given in EAA (2000)(), to obtain a more detailed view of the data quality, the uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)).

| General Comment to reference function | Heated aluminium is forced through one or more dies under extreme force to produce the desired shape. A great number of different shapes, and therefore possible applications, can be achieved by extrusion of aluminium.                                                                                                                                                                                                   |

## 4 Copper and copper alloy forming

Authors: Silvio Blaser, Hans.Jörg Althaus, EMPA Dübendorf  
Review: Roland Hischier

Copper and copper alloys are melted continuously or in batches and cast for the production of shapes suited for the further fabrication step. The cast products are precursors for a variety of materials such as sheets, strips, sections, bars, rods, wires and tubes (IPPC (2001b)).

### 4.1 Sheet rolling of copper

Slabs/cakes of copper or copper alloy are the start material for the fabrication of sheets and strips. The material is preheated in gas or oil fired furnaces, hot and cold rolled and then sent to the finishing operation, which includes re-rolling, cutting to length and width. Surface milling, annealing, pickling, washing and drying are required as intermediate steps to produce high quality strips and sheets.

Hot rolling is usually done with a dual rolling mill equipped with benches up to 200 m and a final coiling device. The cooling water for the rolls has small amounts of lubricant added for improving the attachment to the steel rolls. The vapour generated is vented and the vent gas is de-misted prior to release to atmosphere.

Further cold rolling operations are then performed. Cold rolling results in a hardened metal. In most cases the coil is annealed prior to cold rolling. Annealing is done under reducing conditions to avoid oxidation. A protection gas “exogas” or nitrogen/hydrogen mixtures are used. Exogas is produced at site from natural gas in a special reactor, which is indirectly fired. N<sub>2</sub> and H<sub>2</sub> are purchased and stored at site in special tanks. The N<sub>2</sub>/H<sub>2</sub> protection gas mixtures are produced from the storage tanks by mixing the components in the ratio required. For annealing before cold rolling bell type furnaces are used with electric heating or indirectly fired by natural gas or fuel oil. Tower type furnaces are applied for intermediate annealing of pre-rolled coils.

The sheet thickness is further reduced by stepwise cold rolling operations on different reversing mills. For cold rolling different types of mills called Duo, Quarto, Sexto, Sendzimir (12 rolls) are used. Rolling mill designs as single-stand which are combined to an in-line multi-stand rolling mill are also applied. The combination of the different types applied depends on the thickness of the sheet on the coils and on the finishing status the coil has already been reached which.

During cold rolling an emulsion or oil is used for roll protection. Therefore, the roll stands are vented and the ventilation gases are cleaned by mechanical filters, wet electrostatic precipitators or scrubbing. The emulsion and the oil is cleaned from metal and cracked oil particles are removed by paper or textile band filters.

This description given in (IPPC (2001b)) shows, that the principle for sheet rolling of copper is almost the same of the one for sheet rolling of steel, chromium steel or aluminium. An approximative overview of the process is given in

As no data were available, the infrastructure it is assumed to be the same as for steel rolling. The same amount of infrastructure per volume unit is balanced.

#### 4.1.1 Environmental issues of sheet rolling of copper

The main environmental issues of the refined copper industry are air and water pollution. The facilities generally have their own wastewater treatment facilities and wastewater recycling is usually practised. Most potential wastes are reused. Some local aspects, like noise, are relevant to the industry. Due to the hazardous nature of some solid and liquid waste streams, there is also a significant risk for soil

contamination unless they are stored and handled correctly. Fugitive emissions can be highly significant (IPPC (2001b)).

Fig. 4.1 Copper sheet rolling process; values are copper flows

### 4.1.2 Sheet rolling of copper in ecoinvent

As no data were available in literature for the process of copper sheet rolling, the values for the different in- and outputs are estimated by the values of aluminium sheet production and the hot rolling process of steel.

The background information to the process "sheet rolling, copper" is given in Tab. 4.1, flows are shown in Fig. 4.2.

#### Data quality

Data quality is estimated by filling in the pedigree matrix, according to (Frischknecht et al. (2003)), taking into account the different more or less rough estimations and assumptions by approximating the copper sheet rolling with the values of the aluminium sheet rolling process.

| Included Processes                    | Includes the process-steps: preheating, hot rolling, cold rolling, annealing and finishing. Does not include the material being rolled, only the amount of scrap lost in waste is balanced as primary copper input. Includes the transport of the materials to the plant, but does not include the transport of the product to the customer. |

| General Comment to reference function | The process of copper sheet rolling is similar to the process of aluminium sheet rolling. Also the final outputs are similar in shape, even if the material properties and thus the applications are very different                                                                                                                          |

Fig. 4.2 Flows for "sheet rolling, copper" and their representation in the ecoinvent database (cont.)

## 4.2 Wire drawing of copper

Wire production consists in a first step of wire rod production, which can be compared and approximated by the process of sheet rolling with a smaller degree of deformation. In a second working step, the wire rod is drawn through a series of dies and reduced to its final cross section. The description of this process can well be approximated by the description of steel wire drawing, described in chapter 2.5.

As no data were available, the infrastructure it is assumed to be the same (per volume unit) as for steel wire drawing.

### 4.2.1 Environmental issues of wire drawing of copper

The environmental issues of copper wire drawing, are the same as for the copper sheet production (see chapter 4.1.1).

### 4.2.2 Wire drawing of copper in ecoinvent

No data were available in literature about the production process of copper wire drawing. As the production process can be divided in two main steps, the assumptions and approximations for the balanced values are made separately for these two steps.

The first step, the rolling of the wire rod, is similar to the rolling of the copper sheet. The second is similar in the technique applied, but not in the values resulting, to the drawing of steel wire, because of the greater formability of copper. Values balanced were estimated basing on aluminium and steel forming processes. The background information to the process "wire drawing, copper" is given in Tab. 4.2, flows are shown in Fig. 4.3.

#### Data quality

Data quality is estimated by filling in the pedigree matrix, according to (Frischknecht et al. (2003)), taking into account the different more or less rough estimations and assumptions by approximating the copper wire drawing with the adapted values of the aluminium sheet rolling process.

Tab. 4.2 Ecoinvent meta information for "wire drawing, copper"

| Included Processes                    | Includes the production of wire rod and the further drawing of this to wire. Does not include the material being rolled or drawn; only the amount of scrap lost in waste is balanced as primary copper input. Includes the transport of the materials to the plant, but does not include the transport of the product to the customer. |

| General Comment to reference function | Wire rod production is comparable to sheet rolling leading to another final shape. Further drawing leads to wires with cross sections ranging from 1.6 to 3.5 mm and higher.                                                                                                                                                           |

| Input                    | Process Name                  | Output     | Remarks                                                                                                                                                                                                                      | Category          | Sub-category    | Infra-structure | Location | Modul name in ecoinvent                                            | Mean value | Unit                     | Source for mean value | Type | Standard Deviation | General Comment             |
| Primary Copper           | wire drawing, copper, rolling |            | It is assumed, that for each step, the wire rod rolling and the wire drawing, about 50% of primary material is lost due to scratch losses as it is for copper sheet production. Thus in the same amount is inventoried.      | metals            | extraction      | No              | RER      | copper, at regional storage                                        | 3.96E-02   | kg                       | Estimation            | 1    | 0.08               | (4,5,2,1,3,5,3)             |
| Rolling oil              |                               |            | The wire rod production step requires less rolling oil than sheet rolling (factor 0.8 assumed), due to the smaller degree of deformation. For the wire drawing step the same amount as for sheet rolling is assumed.         | chemicals         | organics        | No              | RER      | lubricating oil, at plant                                          | 7.20E-03   | kg                       | Estimation            | 1    | 0.01               | (4,5,2,1,3,5,11)            |
| Water                    |                               |            | The rod production step needs the same amount of cooling water as sheet rolling, as the material is heated to the same temperature. The wire drawing step requires less water (factor 0.8 assumed) because of friction heat. | resource          | in water        |                 |          | Water, cooling, unspecified natural origin                         | 1.08E-02   | m3                       | Estimation            | 1    | 0.01               | (4,5,2,1,3,5,12)            |
| Fuel Oil                 |                               |            | Basing on the amount of material to be heated. As no data were available about the fraction of oil and gas burners used, the amount of thermal energy is distributed by one half for fuel oil and natural gas each.          | oil               | heating systems | No              | RER      | light fuel oil, burned in industrial furnace 1MW, non-modulating   | 8.00E-01   | MJ                       | Estimation            | 1    | 0.83               | (4,5,2,1,3,5,1)             |

## **4.3 Contouring of brass and bronze**

### **4.3.1 Fundamentals of forming of copper alloys**

“Billets of copper or copper alloy are preheated and extruded and drawn into tubes with a variety of diameters and thickness in a number of “passes”. The drawing machines use a variety of oils and soaps as lubricant that contaminates the tubes and off cuts. The products are normally annealed and degreased before transport and the off cuts are de-oiled in a furnace or other degreasing process before being returned to the furnace for melting.

Copper tubes may be also produced utilising an extrusion press with piercer in which billet sections are extruded to tube shell pieces; the tube shell pieces are then rolled in a breakdown roller (Pilger mill) and finally drawn to size in drawing blocks. The oil utilised (in small quantities) for the drawing operations is neutralised in in-line degreasing/pickling systems often connected with the annealing section.

Products are annealed in a variety of furnaces under reducing conditions using as protection gas “exogas” or hydrogen/nitrogen mixtures.

Wire, tube, strip and some other materials are pickled to produce a bright finish before packing or, in the case of copper wire, to remove oxide from the surface prior to wire drawing. Sulphuric acid solutions are used and sometimes a mixture of dilute sulphuric and nitric acids are used. In the latter case nitric fumes can be emitted if higher strength acids are used.

Surface pickling of sheets and strips is usually performed with sulphuric acid (8 - 10%) but for some special alloys, mixtures of sulphuric and nitric acids are used in continuous lines or automatic systems. Gas cleaning is used to remove nitric acid fumes. The acid is changed from time to time in order to ensure that surface quality is not affected.

Spent acid is sent for treatment and recovery of metal in internal or external treatment plants. The pickling systems are vented for worker protection. The products are rinsed and the rinse water is sent for treatment, sludges are recycled if possible. For surface degreasing of rolled products, detergents containing water are used. The spent water is cleaned by ultra filtration.” (IPPC (2001b))

### **4.3.2 Environmental issues of forming of copper alloys**

Beside the energy consumption of the process, the emissions of metals and hydrocarbons to water from degreasing and pickling are an environmental issue. IPPC (2001b) gives the values in Tab. 4.3 for the annual loads discharged to water from a copper semis production plant. Hydrocarbon emissions are not measured. Emissions of “protection gas” can also be a problem:

“Typical CO production in a shaft furnace used for wire-rod or semis production is 2000 to 11000 grams per tonne of copper. In some installations after-burning is used to remove hydrocarbons from the gases when scrap coated with organic matter is processed. CO is also destroyed at the same time and the emissions are reported to be ~ 45 grams per tonne of copper.” (IPPC (2001b))

### **4.3.3 Contouring of brass and bronze in ecoinvent**

The processes are theoretically modelled according to the information in IPPC (2001b). Most of the values for the flows in these processes are estimated from similar processes since very few quantitative data is available.

The background information to the process "anodising, aluminium sheet" is given in Tab. 4.4, flows are shown in Fig. 4.4 and Fig. 4.5.

### Data quality

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed. The different more or less rough estimations and assumptions are taken into account. Overall data quality is poor.

**Tab. 4.3 Annual loads discharged to water from a copper semis production plant (IPPC (2001b))**

| Emission | kg/a | kg/m3 effluent |
|----------|------|----------------|
| Cu       | 11   | 3.14E-04       |
| Ni       | 3    | 8.57E-05       |

## 5 Zinc coating of steel

Authors: Silvio Blaser, Hans.Jörg Althaus, EMPA Dübendorf  
Review: Roland Hischier

The hot-dip galvanising of steel involves the application of a zinc coating onto the surface of steel by a process wherein the steel is immersed into molten zinc to apply the coating. The zinc reacts with the steel to form the galvanised coatings. The time the steel is immersed in the zinc along with post-galvanising treatment controls the coating thickness, appearance and other characteristics. Hot dip galvanised coatings are applied to steel to improve the anti-corrosion performance of the steel to ensure that it lasts as long as possible with a minimum of maintenance or to provide a decorative appearance. Since zinc has to be heated to a temperature of approximately 455 °C or higher for the galvanising process to be implemented correctly, the process is referred to as a “hot dip” process.

There are two common practices for applying zinc in hot-dip galvanising. One involves the application of zinc onto steel sheet as it is passed as a continuous ribbon of steel through a bath of molten zinc at high speeds. Hence, the term “continuous” hot-dip galvanising.

The other process involves the application of a zinc coating to the surface of steel parts after the parts have been fabricated. This process is not a continuous process in that the parts are immersed as a discrete “batch” into the zinc bath. Hence, the names “batch”, “after fabrication” and “general” galvanising are applied to this process (extracted from Pankert (1997) and internet<sup>6,7</sup>).

### 5.1 Zinc coating of steel coils

The production process is described in (IPPC (2001a)) and two URL-addresses<sup>6,8</sup>.

As mentioned above, the continuous galvanising process is used to describe the application of a zinc coating onto the surface of steel sheet. In the hot dip coating process, the steel is continuously passed through the molten metal, at speeds up to 200 meters per minute. The sheet thickness might be as thin as 0.25 mm or less to as thick as 6.3 mm. In the molten-metal bath, an alloying reaction between the two metals takes place, leading to a good bond between coating and substrate. As the alloy layer is hard and brittle, steel is immersed for a very brief time, in order to keep the alloy layer very thin to accommodate subsequent forming into the final shape. As the strip emerges from the molten bath, it drags out excess metal, much like when an object is pulled rapidly from a container of water. Through the use of an air-wiping process, a controlled amount (thickness) of coating usually expressed as weight of coating per unit area is allowed to remain on the strip surface.

Metals suitable for the use in hot dip coating are those, which have a melting point low enough to avoid any thermal changes in the steel product, like for example aluminium, lead, tin, and zinc. In this study only the case of zinc was analysed.

In general continuous coating lines for sheet comprise the following steps:

- An entry-end welder to join the trailing edge of one coil to the leading edge of the succeeding coil,
- Surface cleaning by means of chemical and/or thermal treatment,
- Heat treatment; annealing furnace to heat the steel to high temperatures to impart the desired mechanical properties (strength and formability) to the steel sheet,

<sup>8</sup> <http://www.galvinform.com/GalvInfoNote%20PDF's/ginote2.pdf>, accessed 03.03.03

- Immersion in a bath of molten metal (zinc for this study),
- Finishing treatment (cooling section, temper mill, tension leveller, surface treatment section and a recoiler).

Continuous wire galvanising plants involve the following steps: pickling, fluxing, galvanising, finishing. Wire is hot dip coated with zinc (galvanised) or tin. Zinc coating is mainly applied as corrosion protection. Tin gives the wire a shine appearance and also provides a solder adhesive layer. As the flows for the two processes are similar, in this study only the continuous galvanising lines for sheets and trips were inventoried. A more detailed description of every single step is given below.

The infrastructure of continuous hot dip zinc coating comprises buildings where galvanising processes take place and for storage, surroundings and machinery fore the single process steps. The assumed lifetime for the infrastructure is 50 years. As no information is available, the infrastructure is approximated by the infrastructure for rolling.

The production of continuous hot dip coating lines in EU 15 was 15 Mt in 1997. The vast majority of coated products, as shown in Fig. 5.1, were galvanised steel.

Fig. 5.1 Production share for different hot dip coatings IPPC (2001a)

### 5.1.1 Entry section

As one coil is being processed through the coating bath, another is being welded to the trailing edge of the first coil. Thus, the process is truly “continuous”, the coating line may indeed operate continuously for days without interruption. No data is available about the welding process therefore it is neglected.

Hot dip galvanising of cold rolled strip is more common than galvanising hot rolled strip. The processing is similar, except that for hot rolled products additional descaling (pickling, to remove hot mill scale) is necessary. Pickling of unannealed cold rolled coil is done for activation. Both processes are done in hydrochloric acid, followed by rinsing. The technology is the same as the pickling process described in the cold rolling section 2.3.1.

It is essential that the surface of the steel coil is free of impurities such as grease, oil or abraded iron fines to ensure the entire surface is exposed to the coating product and strong adherence is achieved. Although degreasing is not necessary when the strip is subsequently heat treated, it is often applied in any case. The cleaning process involves several or all of the following steps:

- Alkaline degreasing via immersion or by spraying; maybe coupled with brushing.
- Alkaline degreasing by an electrolytic system; maybe coupled with brushing.

- Rinsing with water with intermediate brushing between rinsing tanks.
- Drying.

Description is taken from (IPPC (2001a)) and the internet <sup>9</sup>.

### 5.1.2 Heat treatment

From the cleaning section, the strip passes into the heating (annealing) furnace to soften the full-hard strip, to impart the desired strength and formability to the steel and to allow the steel to reach the required temperature before dipping. In the annealing furnace, the strip is maintained under a reducing gas atmosphere to remove any vestiges of oxides on the steel surface. The gas atmosphere is composed of hydrogen and nitrogen. This oxide-reduction step, iron oxide being converted to iron by reaction with the hydrogen, is very important to obtain complete wetting of the steel surface during the short time that it is immersed into the coating bath.

The following types of furnaces are used:

- Sendzimir Furnace; this type of furnace is no longer used in modern coating lines, but some older plants might still operate this horizontal continuous furnace,
- Direct flame furnace (D.F.F; non oxidizing type); this type of furnace cleans the coil surface and does not require any prior degreasing of the metal, but air emissions are generated as the remaining oil from the surface is burnt,
- Radiant Tube Furnace (R.T.F.); this furnace is a variation with indirect heating. The combustion gases circulate through radiant tubes and do not get in contact with the strip. The annealing furnace is combined with an alkaline degreasing equipment.

Fuels used are desulphured coke oven gas and (inventoried in this study) natural gas. Description is taken from (IPPC (2001a)) and the internet <sup>10</sup>.

### 5.1.3 Hot dipping (galvanising)

The exit end of the furnace is connected directly to the molten coating bath metal to prevent the heated steel strip from re-oxidising (in the air) prior to reacting with the molten coating metal. The galvanising bath consists of one or more tanks, usually made of ceramic material. These pots, which can be either fixed or mobile, contain the molten metal at a temperature of 440 – 490 °C, through which the strip is passed. The bath contains zinc and any other required additive (i.e. antimony, lead or aluminium). The bath contains a sufficient amount of molten zinc in order to prevent the wide fluctuations in the operating temperature that may appear under maximum operating conditions. Most pots are nowadays heated by electrical induction systems. However, natural gas as fuel for heating the pots is an alternative.

As the steel passes through the molten zinc bath the surface is coated, to some extent with layers of different iron-zinc alloys, but due to the high speed of the steel strip (max. 180 - 200 m/min) and the short exposure time, the coating (between 20 and 45 µm thick (Frischknecht et al. (1996))) mainly consist of zinc.

Temperature control of the bath is essential, as a high temperature will increase the rate of oxidation at the surface of the molten bath, resulting in increased ash generation. A low bath temperature will increase the viscosity of the molten coating metal, thus inhibiting the formation of a thin coating layer.

<sup>9</sup> <http://www.galvinform.com/GalvInfoNote%20PDF's/ginote2.pdf>, accessed 03.03.03

<sup>10</sup> <http://www.galvinform.com/GalvInfoNote%20PDF's/ginote2.pdf>, accessed 03.03.03

The bath temperature is therefore optimised to meet the individual quality requirements of the final coated product.

In the coating bath, the strip passes around a submerged roll and then exits the bath in a vertical direction. At the exit point, a set of air or nitrogen knives (high pressure air jets) wipe off excess molten metal leaving behind a closely controlled thickness of molten metal. The system is usually controlled by an automatic gauge, which measures the thickness of the coating using X-ray measurement technology or a similar technique. Description is taken from (IPPC (2001a)) and the internet<sup>10</sup>.

#### **5.1.4 Cooling, post treatment and finishing**

The coating is then gradually cooled by air coolers to allow the metal to freeze on the steel surface. Freezing of the coating, or solidification, has to be accomplished before the strip contacts another roll to avoid transferring the coating onto the roll. Thus, coating-process lines usually have a high tower above the coating bath.

Following the coating, the steel strips are usually subjected to post-treatment in order to prevent surface damages and flaws, like white rust caused by water condensation in case of insufficient air access. Voluminous corrosion products as zinc hydroxides (white rust) affect further processing, such as e.g. painting. The formation of condensate during transportation and storage is to be generally prevented.

The resistance against white rust is considerably increased by the application of post treatment, like:

- Oiling; applying a wet film coat with thickness between 0.25 - 3 g/m<sup>2</sup>/side,
- Passivation; a treatment with solvents containing chromic acids, applied by spraying or applicator-rolls, with coat thickness of a few nanometer only,
- Phosphating; applying a phosphate coat of approx. 1 - 1.8 g/m<sup>2</sup>.

To give the steel a special surface appearance, smoothness etc. as required by the customers or to meet width tolerances, the following finishing operations may be applied:

- Mini or No Spangle Treatment; the strip is either cooled more rapidly or steam sprayed with a chemical additive (usually phosphate based) or sprayed with zinc powder,
- Mat Mill; the strip is skin-passed to obtain a mat finish surface.
- For certain applications, an edge cutting must be done in order to obtain the width tolerance needed and to avoid little dog bone defects.

The continuous strip is sheared at the weld that was made at the entry end of the line to remove the weld as well as to maintain coil-to-coil identity. Description is taken from (IPPC (2001a)) and the internet<sup>11</sup>.

#### **5.1.5 Environmental issues of continuous zinc coating process of steel**

Main environmental issues concerning this sub-sector are acidic air emissions, wastes and wastewater; air emissions and energy consumption of furnaces, Zinc-containing residues, oil- and chrome-containing wastewater (IPPC (2001a)).

As wastewater is treated in the factory, post treatment wastewater composition and ancillary products for the water treatment as given in IPPC (2001a) are used to calculate the expenditures and the water emissions of the water treatment process.

### 5.1.6 Continuous hot dip zinc coating in ecoinvent

In (IPPC (2001a)) most values are given in ranges, the mean values are generally calculated as the geometric mean of the given range. When the lower value of the range is zero, then the arithmetic mean of the range is taken (what correspond to half of the maximal value). Values taken from (Frischknecht et al. (1996)) are already mean values and do not have any information about minima and maxima or distribution.

The background information to the process "zinc coating, coils" is given in Tab. 5.1, flows are shown in Fig. 5.2.

#### Data quality

For values represented by the geometric mean, uncertainty is calculated assuming a lognormal distribution and the high value given in (IPPC (2001a)) representing the 95% geometric standard deviation. For the arithmetic means of ranges given in (IPPC (2001a)) and the values from (Frischknecht et al. (1996)), the uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)).

| Included Processes                    | Includes the process steps surface cleaning (by means of chemical and/or thermal treatment), heat treatment, immersion in a bath of molten zinc and finishing treatment. Also includes zinc input and transportation to coiling plant. Does not include the steel strip or sheet being coated.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |

| General Comment to reference function | This module is applicable, if continuous zinc coating (galvanising) of hot or cold rolled strip- or wire-coils has to be inventoried. Data given per tonne of coated product are transformed by dividing them by the mean surface area of 64 m <sup>2</sup> /t (corresponding to ca. 4.2 mm thickness). The zinc coating layer is between 20 to 45 µm thick. The ecoinvent module "zinc coating, pieces, adjustment per um" can be used for adjusting for thinner or thicker zinc layers of coated coils, but it 1.53 µm of it have to be inventoried per um layer thickness adjustment. This is because the zinc consumption per um is higher for coil coating than it is for piece coating. For the chemicals and the zinc, 100 km of 32t lorry transport were inventoried. The softened industrial water is assumed to be produced at the coating plant. Continuous wire coating can be approximated with this module. |

| Uncertainty Adjustments               | Some values are from single or very few plants. For other values no data were available about the percentage of companies represented by the study cited. This was considered in the uncertainties.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

## 5. Zinc coating of steel

| General Flow Information |                                 |                                                    | Representation in ecoinvent                                                                                                                                                                                                                                                        |                  |                              |                 |          |                                                                        |            | Uncertainty Informations |                          |      |                    |                                                           |

Infrastructure for waste water treatment plant is comprised in the infrastructure module. Value for energy use is comprised in the range of uncertainty of inventoried overall energy. |           |              |                 |          |                                         | 6.72E-03   | m3                       | IPPC 2001                |      |                    |                                                           |

Fig. 5.2 Flows for "zinc coating, coils" and their representation in the ecoinvent database (cont.)

## 5.2 Zinc coating of pieces

The production process is described in (IPPC (2001a)) and on the internet<sup>12</sup>.

In a sense, the general or “batch” process is the same as the continuous process in that the objective is to apply a continuous coating of corrosion-resistant zinc onto the surface of steel. However, the practices to achieve this end result are very different.

As stated above, the second galvanising process involves the application of zinc onto a “fabricated” shape. That means, the steel is shaped into the final product, and then dipped into molten zinc to apply a zinc coating. The items to be coated in batch galvanising plants are steel fabrications, such as nails, screws and other very small items; lattice grates, construction parts, structural components, light poles and many more. Tubes are sometimes also galvanised in conventional batch coating plants. These items are coated either one at a time or, in the case of small parts, as a number of parts contained in a “basket”. Hence, the terms “batch” or “after fabrication” are applied to this process.

Galvanising, usually comprises the following process steps:

- Degreasing – physically cleaning and degreasing steel parts,
- Pickling – removing scale, rust, and oxide from steel parts,
- Fluxing – applying a flux coating to reduce surface oxide and allow for the growth of a zinc-iron intermetallic layer necessary for proper galvanising,
- Galvanising – dipping parts in the kettle containing molten zinc and lead.
- Finishing – excessiv zinc removal, cooling, inspection.

A galvanising plant essentially consists of a series of treatment or process baths. The steel is moved between tanks and dipped into the baths by overhead cranes. A more detailed description of every single step is given below.

The infrastructure of batch hot dip zinc coating, comprises buildings where galvanising processes take place and for storage, surroundings and machinery fore the single process steps. The mean lifetime for the infrastructure is 50 years. As no information is available, the infrastructure is approximated by the infrastructure for rolling.

In 1997 the tonnage of galvanised steel was about 5 million. The largest share was produced in Germany with 1.4 million tonnes and 185 galvanising plants (in 1997). Second largest producer was Italy with 0.8 million tonnes (74 plants), followed by UK and Ireland with 0.7 million tonnes (88 plants) and France 0.7 million tonnes (69 plants). The zinc consumption of the EU galvanising industry (excluding Greece and Luxembourg) in 1997 was 381188 t. Galvanised steel is used in construction, transport, agriculture, power transmission and other applications where good corrosion protection and long life are essential.

### 5.2.1 Degreasing of steel

During the degreasing step organic contaminants such as coolants and lubricants are removed from the fabricated steel in a hot alkali solution. These surface contaminants need to be removed prior to pickling so that the surface can be “wetted” by the pickling solution. The steel is dipped in baths containing surfactants, which remove oil and grease from the metal surface by emulsifying. The resulting unstable emulsions float on the surface of the bath and can be removed by gravitational separators, skimmers, micro- or ultrafiltration etc.

---

<sup>12</sup> <http://www.oit.doe.gov/nice3/factsheets/ferrotech.pdf>, accessed 03.03.03

Concentration, bath temperature and immersion time of the work-pieces determine the efficiency of the degreasing baths. The normal temperature range for indirectly heated degreasing baths is 30 – 70 °C, although in some cases hot degreasing is applied at a temperature of about 85 °C. The baths consists of a sodium-hydroxide solution (1 - 10 %) plus other alkaline reagents, such as soda, sodium silicate, condensed alkaline phosphates and borax, and specific surfactants, emulsifying agents and dispersion agents. After degreasing, rinsing is necessary to prevent carry-over of degreasing agents which would shorten the life of pickling baths and reduce the re-usability of the bath.

An alternative method is acidic degreasing; but it is not considered in this study.

Description is taken from (IPPC (2001a)) and the internet<sup>13</sup>.

### 5.2.2 Pickling of steel

Pickling involves the immersion of parts into an acid solution (typically either heated sulfuric acid or ambient temperature hydrochloric acid) to remove surface scale or rust (both oxides of iron), casting skin, roll skin or grid. Therefore a galvanising plant usually comprises a series of pickling baths with different acid concentrations ranging from 2 - 16 %, normally 12 – 16 % when freshly prepared. To prevent excessive pickling of steel items, especially in pickling high tensile steels, and to protect the steel pickling vats, pickling inhibitors (e.g. hexamethylenetetramine) are added to the bath.

During operation the iron content of the pickling bath increases, while the amount of free acid decreases, making it necessary to top up the bath occasionally by adding fresh acid. Iron-(II)-chloride has a limited solubility in HCl. When this maximum is reached, pickling becomes impossible, but usually the pickling bath has to be replaced even sooner at lower FeCl<sub>2</sub> concentrations. Discarding concentrations of 170 g FeCl<sub>2</sub>/l (=75 g Fe<sup>2+</sup> /l) and 100 to 120 g Fe/l have been reported. Raising the temperature of the pickling bath can enable its use at relatively high concentrations of FeCl<sub>2</sub>, e.g. 175 to 200 g/l with the bath at 35 °C, with some increase in emissions.

Pickling in plants with open pre-treatment is usually done at ambient air temperature; plants with an enclosed pre-treatment sometimes operate with higher acid temperatures. Gaseous emissions of the pickling agent can arise from the pickling baths, depending on concentration and temperature of the bath, and from the pickled items. Hydrogen vesicles formed during the pickling process can also contain acid droplets.

Sometimes it is necessary to clean the suspension devices of zinc coatings, to remove faulty coatings from steel fabrications or to de-zinc fabrications whose coatings have to be renewed. This is commonly done by dipping in diluted pickle acid. This process step is called stripping. When pickling and stripping are carried out in the same treatment vat, pickle liquors are created which contain iron- and zinc chloride.

Rinsing is a very important step in the galvanising process as it prolongs the life of subsequent treatment baths, reduces the generation of waste and increases the re-usability of by-products. After degreasing and pickling the fabricated steel is therefore rinsed/dipped in water baths, which are sometimes heated. Water from rinsing can be used to prepare fresh pickling or degreasing baths as a way of recycling water and minimising aqueous blowdown. Description is taken from (IPPC (2001a)) and the internet<sup>14</sup>

### 5.2.3 Fluxing of steel

The purpose of fluxing is to enable liquid zinc to wet the surface of the steel, a necessary prerequisite for the galvanising reaction, and with ammonium chloride-containing fluxes, to provide additional pickling (cleaning of the surface) during hot dipping. At temperatures of above 200 °C the ammonium chloride in the flux decomposes into  $\text{NH}_3$  and  $\text{HCl}$ , which results in an additional pickling effect. Fluxing can be either “dry” or “wet”.

In dry fluxing, the steel is immersed in a fluxing bath, usually an aqueous solution of zinc chloride and ammonium chloride, typically maintained at 40 – 80 °C. Cold fluxing is possible but reduces the potential for air-drying of the work after removal from the flux bath.

Typical bath characteristics are:

- $\text{ZnCl}_2$  150 - 300 g/l
- $\text{NH}_4\text{Cl}$  150 - 300 g/l
- Density: 1.15 – 1.30 g/ml
- Dissolved iron: < 2 g/l

pH of flux baths may be in the range of 1 to 5.0 (normally adjusted to approximately 4.5).

Ammonium chloride in a typical good flux often accounts for 40 – 60 % of the total flux salt. It provides quick drying and better removal of iron oxides from the surfaces of the items, but also causes more fume, ash and dross formation during the coating process. Zinc chloride prevents oxidation of the work-piece surfaces. This is particularly important when the drying time is long.

The iron content of the flux bath is extremely important for process control, economy and environment. To reduce the environmental impact of ammonium chloride during dipping, some galvanisers have changed to 'smoke-reduced' fluxes in which ammonium chloride has partly or completely been substituted by potassium chloride.

After withdrawing the work-pieces from the flux bath, some of the water from the adhering fluxing fluid evaporates. Further drying is sometimes achieved in dedicated drying. Drying of the work helps reduce splashing and ejection of metal from the zinc bath as the work is dipped, a benefit which is increased if the work retains heat after leaving the dryer, i.e. if preheat is applied.

A small number of galvanising works, especially those with exceptionally demanding fluxing requirements for intricate parts, operate an alternative process, called wet fluxing. In this process the fluxing agents flow as a layer of molten salt on the surface of the galvanising bath. Steel parts to be galvanised are passed through the flux layer into the zinc bath. Then the molten salt layer is drawn back from the surface by means of a rake to allow the steel parts to be withdrawn from the galvanising bath without further contact with the flux. Description is taken from (IPPC (2001a)) and the internet<sup>15</sup>

### 5.2.4 Galvanising of steel

The fluxed steel parts are slowly lowered into a bath of molten zinc. The steel reacts with the zinc to form a coating consisting of a series of zinc-iron alloy layers topped by a layer of pure zinc when the parts are withdrawn from the bath. The batch process requires that the part be immersed for much longer times than for the continuous process, typically measured in minutes (up to 30 minutes for the heaviest structural parts), not seconds. There are two reasons for needing longer immersion times. One is to allow the part to reach the bath temperature, because immersion of a relatively cold thick-walled large pipe, for example, means that as the steel is first immersed, it freezes a skin of zinc onto its surface. For the coating to bond metallurgically to the steel, the pipe has to be heated to “remelt” the zinc. Then, additional time is required to develop the iron/zinc alloy bond zone. For most steels, a longer

---

<sup>15</sup> <http://www.galvinform.com/GalvInfoNote%20PDF's/GalvInfo9.pdf>, accessed 03.03.03

immersion time provides a thicker alloy layer (in Frischknecht et al. (1996), values of 65 µm for both-sided and of 130 µm for one-sided coating are given), a thicker alloy bond layer is often desired to provide a longer life to the final product, that is, a longer life before the onset of rust. Like the zinc itself, the alloy layer is galvanically protective to the steel part; thus, a thicker alloy layer means longer life. Yes, the alloy layer is hard and brittle, but since the part is already fabricated, there is no need for additional forming.

The molten zinc has a temperature of 440 – 475 °C. Kettle dimensions vary greatly; typical dimensions are 7 m long by 1.4 m wide by 2.6 m deep. The kettle is normally heated externally, commonly by gas or oil-fired burners.

The zinc bath usually also contains very small amounts of other metals, which either are impurities of the zinc input or are added as alloying elements. A typical bath composition is: Zinc 98.9 wt-%, lead 1.0 wt-%, iron 0.03 wt-%, aluminium 0.002 wt-%, cadmium 0.02 wt-%, traces of other metals (e.g. tin, copper). Aluminium and lead are added because of their influence on the thickness and the appearance of the coating (lead causes the formation of the typical, attractive large spangled surface, which through the years was “the way to identify galvanised coatings”). Lead helps to wet the steel before galvanising and the zinc to flow from the surface after galvanising. In some instances today, bismuth is being substituted for lead to achieve free drainage of the excess zinc. Lead can also be used to protect the kettle. The thickness of the kettle's steel walls is measured on a regular basis to prevent breaking. A small number of plants carry out 'high temperature galvanising' using refractory lined vessels, which allow the zinc bath to be operated at higher temperatures, usually about 530 °C. Description is taken from (IPPC (2001a)) and the internet<sup>16</sup>

### **5.2.5 Finishing**

The steel parts are withdrawn from the zinc bath; excessive zinc is removed by wiping or, in some cases, by rattling. They are then cooled and inspected. Small surface imperfections are repaired and the parts are removed from the jigs and made ready for dispatch. After hot dip coating some steel products are quenched in water to give them special properties. As protection against white rust, the products may be covered with oil emulsions or may be chromated. Other details of variations of this process step for pipes and small components are also reported in (IPPC (2001a)).

### **5.2.6 Environmental issues of the batch process for zinc coating of steel**

The main environmental issues for batch galvanising are emissions to air (HCl from pickling, and dust and gaseous compounds from the kettle); spent process solutions (degreasing solutions, pickling baths and flux baths), oily wastes (e.g. from cleaning of degreasing baths) and zinc-containing residues (filter dust, zinc ash, hard zinc), (IPPC (2001a)).

As wastewater is treated in the factory, post treatment wastewater composition and ancillary products for the water treatment as given in IPPC (2001a) are used to calculate the expenditures and the water emissions of the water treatment process.

### **5.2.7 Hot dip zinc coating (batch process) in ecoinvent**

In (IPPC (2001a)) most values are given in ranges, the mean values are generally calculated as the geometric mean of the given range. When the lower value of the range is zero, then the arithmetic mean of the range is taken (what correspond to half of the maximal value). Values taken from

(Frischknecht et al. (1996)) are already mean values and do not have any information about minima and maxima or distribution.

The background information to the process "zinc coating, pieces" is given in Tab. 5.2, flows are shown in Fig. 5.3

### Data quality

For values represented by the geometric mean, uncertainty is calculated assuming a lognormal distribution and the high value given in (IPPC (2001a)) representing the 95% geometric standard deviation. For the arithmetic means of ranges given in (IPPC (2001a)) and the values from (Frischknecht et al. (1996)), the uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)).

**Tab. 5.2** Ecoinvent meta information for "zinc coating, pieces"

| Name                                  | zinc coating, pieces                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

| General Comment to reference function | This module is applicable, if batch zinc coating of semi-finished steel products, that's shape doesn't change anymore, has to be balanced. Data given per tonne of coated product had to be transformed dividing it by the mean surface area of 60 m2/t. For the chemicals and the zinc, 100 km of 32t lorry transport were balanced. The softened industrial water is assumed to be produced at the coating plant. The coating layer is 65um thick, if the surface is coated on both sides and 130 µm thick, if coating is done on one side only. Due to the fact, that data are given per square meter and not per kg, the energy inventoried for heavy pieces is to low and for light pieces to high. If the data would have been given per kg, the error would have been the contrary. |

| Flocculating agents      | mL           | zinc coating, pieces, Waste water treatment plant | Reference contained no data. Assumption: Same amount per kg product as for coil coating. Aluminium sulphate as proxy.                                                                                                                                                                                                                                                                                                                                | chemicals        | inorganics                 | No             | RER      | aluminium sulphate, powder, at plant                                          | 1.51E-05   | kg                       | IPPC 2001             | 1    | 1.22               | (2,5,1,1,1,3,4)  |  |
|                          |              |                                                   | One part of the incoming cooling and process water leaves the system as treated effluent; it is assumed to be discharged in surface water --> not inventoried. Infrastructure for waste water treatment plant is comprised in the infrastructure module. Value for energy use is comprised in the range of uncertainty of inventoried overall energy. Assumption: ratio between treated and untreated water is the same as for coil coating process. |                  |                            |                |          |                                                                               | 1.67E-03   | m3                       | IPPC 2001             | 1    | 1.22               | (2,5,1,1,1,3,4)  |  |

Fig. 5.3 Flows for "zinc coating, pieces" and their representation in the ecoinvent database (cont.)

### **5.3 Zinc coating of pieces, correction of layer thickness per $\mu\text{m}$**

If zinc layer thickness other than the double-sided 65  $\mu\text{m}$  or the one-sided 130  $\mu\text{m}$  are requested, the amount of zinc needed and the arising heavy metals emissions (evaporating from zinc) have to be adapted proportionally to the  $\mu\text{m}$ -change of layer thickness. The remaining flows depend basically on the coated piece surface area and have therefore not to be changed.

#### **5.3.1 Zinc coating of pieces, correction of layer thickness per $\mu\text{m}$ in ecoinvent**

Per  $\mu\text{m}$  of additional or subtracted layer thickness, the module has to be inventoried one time. This module can be applied also for changing the layer thickness when continuous galvanising of coils is done. In this case the module has to be inventoried 1.53 times per  $\mu\text{m}$  of changed thickness layer, because the zinc consumption per  $\mu\text{m}$  is higher. Data are taken from (Frischknecht et al. (1996)) where no information about minima and maxima or distribution are given.

The background information to the process "zinc coating, pieces, adjustment per  $\mu\text{m}$ " is given in Tab. 5.3, flows are shown in Fig. 5.4.

#### **Data quality**

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed.

| General Comment to reference function | This module is applicable if the coating layer is thicker than the one given for "zinc coating, pieces", or for "zinc coating, coils". Applying it for the latter, the module has to be multiplied by the factor 1.53 for correct use. The Dataset is not applicable for thinner coating layers. Data given per square meter of product surface corrected by one $\mu\text{m}$ . |

## 6 Welding

Author: Hans.Jörg Althaus, EMPA Dübendorf  
Review: Roland Hischier

### 6.1 Definition and fundamentals of welding

Welding is defined (DIN 1910, Part 1: 07.81 and ISO 857: 1990) as the bonding of several parts made of the same or different materials to form a single unit, where, in the weld region, either the temperature is raised to the melting point, the parts are pressed together, or both. Weld filler materials are also used as necessary. The welded joint can be separated only by destroying it. This definition applies to the welding of both metals and thermoplastic materials (Brandt & Weiler (1997)).

Weldability (see DIN 8528, Part 1: 06.73): A component fabricated by welding is weldable if, after fabrication, it fulfils all the functions required of it at its point of use for the duration of its expected lifetime. It is not weldable if it does not fulfil these functions as a result of any defects arising from a welding process. One of the most important preconditions for a good welded joint is that impurities on the surface of the workpiece such as thick scale, rust, oil, and paint should be removed as completely as possible. It is certainly possible to weld over a protective coating, but this can affect the integrity of the weld (Brandt & Weiler (1997)).

The methods of welding metals can be divided into two groups:

In fusion welding of metals, the junction area is melted to form a pool of molten metal, which consists of parent metal, either alone or with added filler metal (minus metal lost in the process). The zone surrounding the molten pool is to a greater or lesser extent affected by changes to its structure and properties, depending on the degree and duration of heating and the rate of cooling. This depends on the heat flux, which in turn is very dependent on the welding method.

In compression welding of metals, the workpieces are pressed together at the welding region, and, in most processes, are also heated. The heat is applied by various means, e.g., electrically (resistance or induction heating), or by flames (Brandt & Weiler (1997)).

This study concentrates on the fusion welding, differing between gas welding of steel, arc welding of steel and arc welding of aluminium. Fig. 6.1 shows the different processes and sub-processes of the fusion welding.

Fig. 6.1 Fusion welding processes (Brandt & Weiler (1997)).

### 6.1.1 Environmental issues of the welding process

Environmental issues in the welding process are mainly discussed in literature from a point of view of health and safety for the welder. Incorrect operation of a welding process can lead to hazards to personnel, especially from electric current, atmospheric pollutants (smoke, vapours, and gases), radiation, and noise. Precaution against fire and explosion is also very important. Fire can be produced directly by flames, or can begin slowly due to unnoticed molten material impelled over long distances, often only becoming serious after some hours. Fuel gases (e.g. acetylene, propane, etc.) and oxygen, constitute the main source of danger for explosions.

The concentrations of atmospheric pollutants such as airborne particulates (fume), vapours, and gases must not exceed the legal limits, i.e., the MAK ("Maximale Arbeitsplatzkonzentrationen"; maximal concentration on the workplace) values. Those limits are only valuable to guarantee human health when workers are exposed to the harming gases during the workprocess. They are not setting limits and they don't tell anything about the environmental pollution itself, because they can be maintained simply by diluting the concentration by mixing the polluted air with fresh air.

The airborne particulates contain lead, chromium, cadmium, nickel, mercury, copper, and zinc. They are formed as metal vapour during the processes of welding and soldering, and usually become oxidised and suspended in the air as fine dust. The harmful gases formed can include nitrogen oxides (NO, NO<sub>2</sub>) from flames, ozone and sometimes phosgene from the intense light emitted by electric arcs, and carbon monoxide when welding with a carbon dioxide gas shield.

## 6.2 Manual Gas Welding of Steel

In manual gas welding (or autogenic welding; descriptions taken from Brandt & Weiler (1997)) the heat required is produced by burning a mixture of acetylene and oxygen. The flame impinges directly on the welding area, and the filler metal is fed by hand.

In manual gas welding, the rate of heat flow to the workpiece is low compared with other welding methods, and the process is comparatively slow. For this reason, and because of the high thermal conductivity of metal, the structure of the neighbouring parent metal is considerably affected. In spite of its disadvantages, ca. 10% of all welding is by the autogenic method.

The autogenic torch is simple, lightweight, and cheap. It is much used for repairs and for simple jobs in the workshop. The gas supply consists simply of oxygen and acetylene bottles with tubing to convey these gases to the welding area. The main uses of autogenic torches are for welding pipelines in chemical plant construction, general industrial plants, shipbuilding, and heating plants, where its value depends more on the manual skill of the welder than on high melting rates.

Acetylene is used exclusively as the fuel gas in gas welding, as of all the hydrocarbons it has the highest heat of formation per unit mass, and gives the highest combustion temperature (Fig. 6.2), combustion rate, and hence heat flux and heat transfer from the flame to the workpiece. This is especially useful for the rapid heating of small surfaces. To prevent scaling and decarburization of the workpiece, the acetylene flame is adjusted to a neutral state, i.e., with no excess of either oxygen or fuel gas (volume ratio of oxygen to acetylene ca. 1.05). The rest of the oxygen required by the stoichiometry is provided by the surrounding air.

Fig. 6.2 Temperature profile along the flame axis when burning acetylene and propane Brandt & Weiler (1997).

As autogenic welding is done manually with no or very little infrastructure- and material demand for the machinery, those inputs are neglected in this study.

### 6.2.1 The manual gas welding process of steel in ecoinvent

For a lack of information on acetylene and oxygen consumption and on emissions the following assumptions are made:

The amount of acetylene used is estimated assuming that the energy needed for gas welding is five times the energy needed for automated arc welding (MAG). The heating value of acetylene is 51.2 MJ/kg (Bach et al. (1999)).

The volume ratio of oxygen / acetylene = 1.05. Thus the mol ratio of oxygen / acetylene also = 1.05. With the molar weight of  $O_2 = 32$  g/mol and of  $C_2H_2 = 26$  g/mol the mass ratio of oxygen / acetylene is calculated to be  $32 / (26 \cdot 1.05) = 1.17$ .

The metal, the nitrogen oxide and the ozone emissions are taken from the MAG welding process.

The CO and  $CO_2$  emissions are calculated to reflect the formation by the acetylene burning. Because of the neutral to slightly reducing conditions chosen for welding, the CO /  $CO_2$  ratio is rather high. It is assumed to be 1:100 (mol/mol). Thus per kg (= 38.46 mol) of acetylene burned 3.35 kg  $CO_2$  (= 76.16 mol) and 0.021 kg CO (= 0.7616 mol) are formed.

Furthermore it is assumed that 1% of the acetylene is emitted to air by lighting the torch and changing the bottles.

The transports of the steel feed and gas is inventoried according to the quality guidelines (see Frischknecht et al. (2003))

The background information to the process "welding, gas, steel" is given in Tab. 6.1, flows are shown in Fig. 6.3.

### Data quality

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed.

### 6.3 Arc welding of steel

The following description of the welding processes is taken from Brandt & Weiler (1997). A good overview of the arc welding process in German language is given in Nies (1992).

In arc welding the heat source is the electric arc between the welding electrode and the workpiece. The arc may be exposed, but is then nearly always surrounded by a gas shield (see below), or it may be covered by a layer of powder (submerged arc welding). In both cases, access of air (oxygen, nitrogen, and water vapour) is restricted.

Protective gases are either inert (almost exclusively argon), reactive (carbon dioxide), or mixed gases with a high proportion of inert gas, e.g., argon, and 1–9 vol.% oxygen or 18 vol.% carbon dioxide. These not only have a protective effect, but in some cases a metallurgical effect also.

Welding powders used in the submerged arc process (DIN 8557, Part 1: 04.81 and EN 756: 1992) stabilise the arc and reduce the rate of heat loss and also have a protective effect. Metallurgical effects include deoxidisation, prevention or replacement of burn-off losses, and sometimes addition of alloying elements. The powders consist mainly of oxides of silicon, manganese, calcium, barium, magnesium, titanium, sodium, potassium, and iron, and also some fluorides, e.g., of calcium and sodium/aluminium. The many types of powder can be classified according to their principal components (manganese silicate type, calcium silicate type, basic aluminate type, etc.).

The electrical energy is fed to the arc from controllable and variable sources of electric current, e.g., transformers, rectifiers, or converters. Arc welding processes operate at a higher heat flow rate than gas welding, so that higher welding and melting rates can be achieved and the heat-affected zones are less extensive.

There are several different types of arc welding processes (see also Fig. 6.1).

#### Manual Arc Welding

In manual arc welding with coated electrodes, the arc is formed between the melting end of the electrode and the workpiece, causing the coating to melt and partially vaporise. The weld pool and the molten droplets during transfer to the workpiece are protected from the surrounding air by the gases produced from the coating.

The coating also performs a number of other functions:

- It facilitates metallurgical reactions that clean the weld pool
- It stabilises the arc
- It compensates for the loss of alloying elements from the cored wire and the parent metal
- It can introduce seed nuclei into the weld pool and hence grain refine the weld metal
- It can control the basicity or acidity of the melt
- It can alloy with the material of the welded joint and hence modify its chemical composition

Cored wire is usually used to achieve a composition that matches that of the alloy being welded as closely as possible. The special requirements of manual electrodes are met with the aid of the coating used. The coatings on manual welding electrodes have compositions similar to those of submerged arc welding powders, and usually contain silicon, manganese, calcium, titanium, magnesium, aluminum, potassium, and sodium, as well as gas formers such as cellulose for certain applications.

Two important types of steel electrode are:

- The rutile (titanium dioxide) type with a high proportion of titanium dioxide in the coating, with which simple manual welding tasks can be quickly carried out

- The basic lime (calcium carbonate) type with a high proportion of calcium carbonate in the coating, which can produce welds with the best quality characteristics, especially toughness

High-performance electrodes have coatings containing a high proportion of metal in powder form. These give a higher melting rate than normal electrodes for the same electricity consumption.

### **Welding with Cored Wire**

Cored wire is a tubular metal electrode filled with material similar to that used for the coating on normal electrodes. Its particular advantage is that it can be fed from a long coil, and can be welded continuously. This gives a faster average welding speed than with manual electrode welding. During welding, the cored wire slides through a burner close to the welding area. Shielding gas can also be injected. The use of cored wires containing gas-producing substances can enable welding to be carried out without a gas shield under difficult conditions, e.g., in wind.

### **Tungsten Inert Gas (TIG) Welding**

In these processes, the arc is formed between the tip of an infusible tungsten electrode and the workpiece. The function of the electrode is only to conduct electricity and produce the arc. The filler metal is fed to the weld pool from one side, either by hand in rod form or by an automatic system as wire. Argon is usually used as the protective gas, occasionally helium or argon–helium mixture. The tungsten electrode is alloyed with up to 4% thorium dioxide to reduce the work of electron emission at the tip of the electrode and to increase the maximum current.

Welds of the highest quality can be produced by TIG welding. It is best to use direct current with the workpiece as the positive pole when welding high-alloy (chromium–nickel) steels, nickel-based alloys, titanium, zirconium, tantalum, and their alloys. Alternating current is used when welding metals that form high-melting oxides, e.g., aluminium and its alloys, as continuous reversal of the current direction continuously removes the oxide film from the weld pool.

Pulsed current arc welding is a variation of the TIG process. This is very useful for welding thin sheet metal, as it minimises the extent of the heat-affected zone and hence the distortion of the sheet. The weld pool is so small that dripping of molten metal does not occur, even when welding in difficult situations. For high-quality TIG welding, transistorised pulsed current welding robots are available that can be very precisely controlled by a variety of computer programs.

### **Plasma Welding**

With the plasma arc, the gas rate is usually much higher than with the TIG arc. Also, the temperature of the arc is increased by a factor of 2–4 and the energy density by a factor of ca. 10. This is achieved by greatly constricting a TIG arc together with the protective gas stream surrounding it with the aid of a water-cooled copper nozzle, forcing the entire gas stream to pass through the arc.

In plasma welding, the plasma jet is always surrounded by a protective gas layer. As the plasma jet usually penetrates into the sheet, the result is a key-lock effect similar to that produced by autogenic rightward welding. There is an upper limit to the weldable sheet thickness, but the welding speed is significantly higher than in other arc welding processes. The amount of heat applied per unit length of weld is small.

A very wide range of power outputs can be used in plasma welding, and the process can therefore be used for sheet thicknesses in the approximate range 0.01–10 mm. So-called microplasma welding is a low-power process using an "untransferred" arc, i.e., between the tungsten electrode and the nozzle wall. In the medium to higher power range, the plasma welding arc is "transferred," i.e., it is between the tungsten electrode and the workpiece. The usual plasma gases are argon and hydrogen.

Plasma welding is also used for resurfacing metal, which can be plated over large areas to a thickness of ca. 2–8 mm. It is mainly used in the construction of chemical equipment. There are two variations: plasma welding of powder coatings and plasma welding of wire.

In plasma welding of powder coatings, the powder is fed from a holding vessel to the plasma stream, where it melts. In the hot wire process, two wires are fed in parallel to the welding zone. Electric current from an auxiliary source is passed through the wires, heating them (because of their ohmic resistance) to a temperature just below their melting point close to the welding zone. The plasma burner oscillates and can therefore apply metal to a wide fusion zone.

### **Metal Inert Gas (MIG) and Metal Active Gas (MAG) Welding**

In MIG and MAG welding, high-power processes, the arc is produced between a wire electrode, fed from a coil, and the workpiece. This method of supplying the electric current gives a high electrode current density (ca. 100 A/mm<sup>2</sup>) and hence a high melting rate.

The wire electrode is fed to the electric arc by a motor whose speed can be varied according to the wire diameter and electric current. The current to the welding wire is fed through a tubular contact in the "welding pistol" close to the arc. Only direct current is used in the MIG and MAG process, the electrode usually being the positive pole. The metal is then transferred as small droplets and penetration is deep. If the electrode is negative, larger drops of metal are transferred and there is less penetration.

The difference between MIG and MAG lies in the gas used:

- The metal inert gas (MIG) process uses an inactive, i.e., noble gas shield
- In the metal active gas (MAG) process the protective gas is active, e.g., carbon dioxide or mixtures or argon with carbon dioxide and/or oxygen is used

The MIG process, with argon (or sometimes helium) as the protective gas, can be used to weld workpieces of thickness >3 mm made of non-ferrous metals and alloy steels. With pulsed direct current of variable magnitude and pulse frequency, the transfer of droplets can be controlled. In this pulsed arc or pulsed MIG process, each pulse of current causes a droplet of metal that has been melted in the background current phase to be thrown off. The droplet size and frequency can be influenced by the type of pulse used. The pulsed MIG process is very suitable for welding in difficult situations.

The MAG process is mainly used for welding plain carbon and low-alloy steels. As the protective gas has an oxidising effect, the filler metal must contain a high proportion of deoxidising components (e.g., manganese, silicon, aluminium). The metallurgical reaction that takes place gives increased nucleation and hence grain-refined weld metal.

### **Sources of Electric Current**

Power transistors are increasingly used for controlling the electric current. They can be used as digital switches or analog regulators. As their power losses are higher, analog regulators are used mainly for lower-power equipment. As switches (high frequency), they can be in the primary or secondary circuit, i.e., the transistors can be between the mains supply and the transformer or the transformer can be between the mains and the transistors. With the first arrangement the equipment is lightweight, but very sensitive to voltage peaks. Equipment of the second type is heavier.

### **Submerged Arc Welding**

In submerged arc welding, the arc produced between the automatically fed filler wire and the workpiece is covered by powder, and is located in a cavity formed within powder that has become molten. The powder flows in the direction of welding, preceding the welding zone of the metal sheet. Only a

small amount of powder is consumed by the welding process, and the unused powder is sucked away and reused. The powder blanket essentially performs the same function as the coating on manual electrodes. The welding speed is high, and in equipment with several filler wires the melting capacity is also high. The process can be used only in situations where the sheet metal is not steeply sloped.

### **Narrow Gap Welding**

Heavy section workpieces can be joined economically and with minimum effect on the parent metal by the so-called narrow gap welding process. The best of the various methods for filling a vertical narrow gap with weld metal is the MIG/MAG process. In this gas-shielded process, the filler wire and protective gas are cooled in a sword-shaped sheathed tube and fed to the welding point in the narrow gap. There are two systems:

- Two wires, which have been subjected to plastic deformation to give a predetermined internal stress, are guided into the two corners of the welding gap, giving a defect-free root position
- In the second system, a wire preformed to a waved shape so that it alternately fills each corner of the region to be welded inside the narrow gap performs this function.

Narrow gap welding can also be carried out by the submerged technique. While gas-shielded narrow gap welding can be used for gap widths of ca. 10 mm, the gap must be wider for submerged welding.

#### **6.3.1 Automated arc welding of steel in ecoinvent**

The module provides values per meter weld seam by MAG-welding with a mixture of 83% Ar, 13% CO<sub>2</sub> and 4% O<sub>2</sub> as protective gas. The gas demand is 16 l/min. The low alloyed steel wire is 1.2 mm in diameter and 6 m/min is used. The welding speed is 1 m/min<sup>17</sup>. Thus the consumption of wire per meter of weld seam is 0.0536 kg.

The power consumption is calculated based on the value given in Künniger & Richter (1997) and the assumption that the energy input corresponds linearly to the amount of wire used. The emissions (except for the particulate emission that is calculated as the sum of all the metal emission) are given in Künniger & Richter (1998).

The transports of the steel feed and gas is inventoried according to the quality guidelines (see Frischknecht et al. (2003))

For the source of power (infrastructure) the unspecific electronic device is used as proxy. A value of 1E-5 kg/m is assumed (this value corresponds to the life time production of 10 km of weld seam per kg power transistor).

The background information to the process "welding, arc, steel" is given in Tab. 6.2, flows are shown in Fig. 6.4.

### **Data quality**

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed.

| General Comment to reference function | Different arc welding technologies can have very different emissions. Only to be used for the technology describes or as a rough proxy if welding is not important in the system considered. |

## 6.4 Arc welding of aluminium

This chapter is mainly based on Brandt & Weiler (1997):

The main problem in welding of aluminium is dealing with the film of aluminium oxide scale which adheres extremely strongly and has a very high melting point. As the thermal conductivity of aluminium metal is also very high, there must be an ample heat supply so the weld pool does not solidify too rapidly or contain nonmetallic particles or gas-filled pores.

The simplest process, welding with manual electrodes, is widely used and is completely satisfactory for simple joints. Qualitatively good welds can be produced by the TIG and MIG processes. The preferred protective gas is helium. The alternating current removes the layer of aluminium oxide. If the weld is carefully prepared and the auxiliary materials have been correctly chosen (surface cleanliness), mechanically sound low-porosity welded joints are obtained. Recent investigations have indicated that high-power processes such as submerged arc welding are also suitable.

Owing to the low melting point of aluminium, the low viscosity of the molten metal, and the small difference in density between the metal and its oxide, manual welding of aluminium and its alloys needs highly skilled welders.

### 6.4.1 Arc welding of aluminium in ecoinvent

Because no quantitative information on aluminium arc welding could be obtained, the following assumptions are made:

The volume of filler rod used is estimated to be the same as for MAG welding of steel, i.e.  $6.79 \times 10^{-6} \text{ m}^3$ . Thus 0.0183 kg/m weld seam of filler rod is used. The filler rod is assumed to be composed of 90% Al and 10% Si.

Energy consumption is calculated from the current and the voltage commonly used for aluminium MIG welding<sup>18</sup>. With 150 A and 15V a power of 2250 W are obtained. Assuming a welding speed of 0.5 m/min the energy consumption is calculated to 75 Wh/m weld seam.

Helium is assumed to be used as protective gas. A flow of 10 l/min is assumed. Thus 20 l/m weld seam helium is consumed.

The total particulate matter emissions are assumed to be as high as for MAG welding of steel. The composition however is different. Zn, Al and Si are thought to be dominant. We assume 60% Al, 30% Zn and 10% Si.

The background information to the process "welding, arc, aluminium" is given in Tab. 6.3, flows are shown in Fig. 6.5.

### Data quality

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed. The data are based on rough estimations and of poor overall quality.

## 7 Enamelling

Author: Niels Jungbluth, ESU-services, Uster

Review: Mischa Classen, Hans-Jörg Althaus, Rolf Frischknecht

### Acknowledgement

We thank Gabriela Lowitz for the information provided in a personal communication.

### Summary

Enamel is a glass of a particular chemical composition and physical nature determined for the surface protection of metal. The major interest for the enamelling process in this database is the application for hot water boilers. The inventory has been elaborated for the European situation. The basic inventory is split up into the major process stages degreasing, corroding, cleaning and firing as well as an inventory for the materials used for enamelling. The life cycle inventory is based on the data investigated in a study for the new single layer enamelling process. General assumptions are used for transport distances. The inventory of enamelling can be considered as a basis for the assessment of this process in connection with technical applications.

### 7.1 Introduction

Enamel is a glass of a particular chemical composition and physical nature determined for the surface protection of metal. This results in a composite material of glass and metal, which combines positive qualities of both materials. The process of firing this glass on metal is called enamelling and thus the object, which has had its surface protected and improved, is referred to as enamelled (Wendel-Email (2002)). Some of the early vitreous enamelled relics date back to the 13th Century BC (IVE (2002)).

The word enamel comes from the High German word “smelzan” and later from the Old French “es-mail”. In American English it is referred to as Porcelain Enamel. It should not be confused with paint, which is sometimes called ‘enamel’. Paints cannot be enamel. They do not have the hardness, heat resistance and colour stability that is only available with real vitreous enamel (IVE (2002)).

### 7.2 Resources of Enamel

First of all an enamel frit is melted from natural and synthetic materials in furnaces. Silica sand (40%-49%), boric anhydride (15%-17.5%) and sodium monoxide (15%-17%) are the major ingredients of enamel frits (Lowitz (1998)). After that, it is ground to become enamel slurry or powder enamel. Depending on the nature and size of the object to be enamelled, the metal pieces get a wet or a dry application of enamel. This is done by dipping, spraying, pouring, flooding or powdering. Afterwards the objects are fired at temperatures of between 550°C and 1,000°C.

### 7.3 Characterisation of the Product

The smooth glass-like surface is hard; it is scratch, chemical and fire resistant. It is easy to clean and hygienic (IVE (2002)).

### 7.4 Application of Enamels

One can recognise enamel as the material used to produce the now highly collectable advertising signs produced during the early 20th Century. The “Hovis” and “Virol” signs were part of the everyday street scene. Cook stoves will almost certainly have a vitreous enamelled oven and the higher quality

cookers will use it on the outer parts. A cast iron or steel bath may also have been vitreous enamelled. Less obvious are the storage silos on farms, usually blue or green (IVE (2002)).

Enamel is become more used as a protective coating for hot water tanks, like solar boilers and water heaters, since the availability of appropriate powder application equipment for such products (Ditmer (2002)).

Due to its mechanical, thermal, optical and chemical properties, enamel offers a good surface protection for any enamelable metal. Not only can metals be protected against corrosion by being enamelled, but they can also be made more interesting by the use of colour (Wendel-Email (2002)). Vitreous enamel can be applied to most metals. For jewellery and decorative items it is often applied to gold, silver, copper and bronze. For the more common uses, it is applied to steel or cast iron. There are some specialised uses on stainless steel and aluminium (IVE (2002)).

## 7.5 System Characterisation

Fig. 7.1 shows a typical layout of a modern powder enamelling plant for hot water tanks. This plant has a production capacity of circa 100 -120 products / hour and consists of the following equipment :

- Shot blaster
- Powder enamel system
- Automatic transfer device
- Enamelling furnace
- Cooling tunnel

Fig. 7.1 Layout of a powder enamelling plant for hot water tanks (Ditmer (2002)).

The boilers are loaded onto a conveyor near the testing station after the welding department and then they are transported to the shot blaster. They remain stationary in front of the sliding doors until this machine is ready for operation. The doors will open automatically at the end of each cycle and the boilers will move to the blasting positions where they are clamped into a centring device. During the

first stage the boilers will be centred and rotated, while a rigid multi nozzle lance enters the product to blast the interior. Remaining shot medium will be washed away by means of compressed air during the next stage. At the end of this cycle boilers will be moved to the automatic powder application system, which also comprises of two stages (Ditmer (2002)).

At the first stage the boilers will be centred while the interior is sprayed with powder enamel by means of extended automatic guns mounted on a PLC controlled reciprocator. At the second stage, the spraying operation will be repeated in order to obtain the required enamel layer thickness. An automatic transfer unit picks the boilers one-by-one from the pre-treatment / application conveyor and places them carefully on the furnace conveyor (Ditmer (2002)). Fig. 7.2 shows a picture of an enamelling plant for hot water tanks.

Fig. 7.2 Picture of an enamelling plant for hot water tanks (Ditmer (2002)).

## 7.6 Life Cycle Inventory of Enamelling

The environmental impacts of enamelling processes have been investigated by Lowitz (1998), right side of Tab. 7.1). Three different processes were investigated in this Ph.d. thesis per  $\text{m}^2$  of enamelled steel sheet:

- At the time of investigation the major process used two stages with a basic and an upper enamel coating which is fired in two production stages. The enamel use is together  $710\text{g}/\text{m}^2$ .
- An improved process uses also two layers which are fired in one process. The enamel use is together  $390\text{g}/\text{m}^2$ .
- A new production process uses only one enamel layer and one firing process. This powder coating technology is used in the meantime by many manufacturers. The enamel use is  $600\text{g}/\text{m}^2$ .

The life cycle inventory is based on the data provided by Lowitz (1998) for the new single layer enamelling process. According to an actual statement of the author this is the most important process in the mean time. They have been investigated from 1993-1998 in Germany. Further information about the type of steel sheet were not available.

Tab. 7.1 shows the unit process raw data and the data investigated by Lowitz (1998). The major interest for the enamelling process in this database is the application for hot water boilers. An important share of enamelled boilers is imported to Switzerland from different countries. Thus the inventory has been elaborated for the European situation.

The basic inventory is split up into the major process stages degreasing, corroding, nickel-plating, cleaning and firing as well as an inventory for the materials used for enamelling. According to the information provided by an expert<sup>19</sup> is the process of nickel-plating not used for the enamelling of boilers (which are the major product of interest). It has thus not been considered for the inventory.

Gas, oil and electricity are used as energy carriers by different manufacturers, but the share of these energy carriers in today plants was not known. Lowitz (1998) assumed that all energy is delivered by electricity which was at this time the dominating energy used. The energy for the pre-treatment processes was not split up to the different stages. For some special chemicals there are no background data available. Their use has been assessed with the generic data for organic or inorganic chemicals. Transports of materials are calculated with the standard transport distances. Data for some process specific emissions are also shown in the study of Lowitz (1998). They are considered for the unit process raw data.

Data for the infrastructure and land use of such facilities were not available. They have been roughly assumed with data for a metal coating plant. More Information about threshold limits for effluents and air emissions in Germany can be found in dev (1999). But, it was not possible to relate these information to the functional unit investigated in this inventory. Further background information for the enamelling process is given by Petzold (Petzold & Pöschmann (1992)).

## 7.7 Data Quality Considerations

Tab. 7.1 shows the data quality indicators for the inventory of the enamelling process. The simplified approach with a pedigree matrix has been used for calculating the standard deviation. The inventory is based on an estimate for the process at a time when it was new and not in common use. Nowadays it became the standard procedure. Large uncertainties exist for data for transport distances of materials. Other types of energy use are also possible for this process. Thus in general the data quality is not very reliable.

## 7.8 Conclusions

The inventory of enamelling can be considered as a basis for the assessment of this process in connection with technical applications. It is not meant to be used for the direct comparison of this process with alternative processes. For that, detailed information about product properties and type of application would be necessary.

|                    | 402 | IncludedProcesses          | The basic inventory is split up into the major process stages degreasing, corroding, cleaning and firing as well as an inventory for the materials used for enamelling. All stages of enamelling are summed up not including the metal sheets treated. Data for infrastructure and land are estimated roughly with data for a metal coating plant. |

## 8 Selective Coatings on Metal Sheets for Solar Absorbers

Author: Niels Jungbluth, ESU-services Ltd., Uster

Review: Hans-Jörg Althaus, Rolf Frischknecht

### Acknowledgement

The investigation of different selective coatings for solar absorbers took place in a difficult market. The last years have shown a high competition between different coating technologies and manufacturers. Environmental arguments played an important role in this competition and thus different manufacturers were sceptical in providing data or information for our background study. We thank Davorin Pavic und Thorsten Heinze, Interpane Solar Beschichtungs Gesellschaft, V. Handke, IZT, Berlin, Michael Grupp, Alanod Aluminium-Veredlung GmbH & Co, Dr. K. Raghunathan, IPTE, Kai Bohn, ChromeCoat A/S, Mr. Rossy and Mr. Roulet, Energie Solaire SA, CH, Billy Byrom, Aetsolar, US, Alternat Energy Technologies LLC, US and other persons of different manufacturers for the information provided in a personal communication. Thanks are also due to Paul Gantenbein, SPF Rapperswil for his comments on the manuscript.

### Summary

In order to reduce the energy loss through heat emission, solar absorbers have a spectrally, selective surface coating on the metal sheet. This chapter investigates unit process data for selective coatings made by vacuum deposition and wet processes. Information provided by different manufacturers are the basis for the gate to gate inventories per m<sup>2</sup> coated material. The inventory for the sputter or black chrome coatings on copper and stainless steel and the aluminium oxide-based layer pigmented with colloidal nickel process is based on a reliable environmental report or data provided by producers with figures for all known relevant energy and material uses and emissions. Data for the physical vapour deposition process and the Black Majic on copper are only rough estimations with known data gaps for the use of materials. The inventories of metal coating processes can be considered as a reliable basis for the assessment of this process in relation to the production of the whole solar absorbers.

A direct comparison of different selective coatings based on these data is not possible. Some environmental aspects could not be quantified for some processes. System boundaries differ for the different processes investigated. A comparison makes only sense for the amount of heat delivered by different solar absorbers including the production and dismantling of these appliances and not for the coating process alone. Thus the product properties (e.g. absorption and emittance, life time, further materials, etc.) of the solar collector have to be taken into account if a comparison for solar absorbers with different coatings is made based on the data investigated here. The analysis of solar systems shows that coating has a minor impacts in comparison to the other components of the system.

### 8.1 Introduction

Solar absorbers are usually black, as dark surfaces demonstrate a particularly high degree of solar light absorption. The level of solar absorption ( $\alpha_{\text{sol}}$ ) indicates the amount of solar radiation being absorbed that means not being reflected. As the absorber warms up to a temperature higher than the ambient temperature, it gives off a great part of the accumulated solar energy in form of long-wave heat radiation. The ratio of absorbed energy to emitted heat is indicated by the degree of emission. The loss of heat energy in the long wave length is increased by heat radiation (Solarserver (2002)).

In order to reduce energy loss through heat emission, efficient absorbers have a selective surface coating. This coating enables the conversion of a high proportion of the solar radiation into heat. The coat-

ing influences not only the solar absorption of the surface (efficiency of collecting the radiation), but also the emission (how easily the surface emits the longer wavelength infrared radiation). Commonly quoted parameters of performance for solar selective surfaces are solar absorption ( $\alpha_{\text{sol}}$ ) and thermal emittance ( $\epsilon_{\text{th}}$ ). The usual coatings show a solar absorption of over 0.9.

Galvanic selective coatings include black chrome on copper and stainless steel, black nickel, and aluminium oxide with nickel. Another type of wet process is the Black Majic coating. Vacuum deposited coatings include sputter coatings on copper, physical vapour deposition (PVD) coatings on aluminium and titanium-nitride-oxide layer. Solar paints which can be mechanically applied to the absorbers (with either brushes or sprays), are less or not at all selective, as they have a high level of emittance.

The last years show a great shift in the share of different coating technologies. With a high competition on the market, environmental arguments played an important role in the marketing strategies of some companies. Thus there was some sceptics in providing data for a report like this.

This chapter investigates different selective coating procedures for metal sheets. Only the process, but not the substrate coated are included in the inventory. The aim is to investigate background data for the environmental impacts of the coating processes. Nevertheless, as the end consumer buys a solar collector and not a coating a direct comparison of the environmental impacts per square metre doesn't make much sense. But these data are used to investigate the environmental impacts of different solar collectors including all necessary materials and processes (see Jungbluth (2003)).

## 8.2 Resources used for Selective Coatings

Only small amounts of materials (mainly metals used as substrate) and chemicals (mainly acids) are directly used for the coating process. For the final product, the solar absorber, materials like steel or copper are used in much higher quantities (Jungbluth (2003)).

## 8.3 Characterisation of Metal Coatings

Tabor (1955) introduced the use of spectrally selective surfaces for solar collectors, and several types of selective surfaces have been developed since. Several coating methods to prepare selective surfaces are used in the manufacture of solar absorber. A good overview for the processes used by different producers is given by (Remmers (1998)) and (Lampert (n.d.)). Tab. 8.1 shows the main characteristics of different processes.

Tab. 8.1 Characterisation of processes to make selective coatings

Oxide coatings were the first type of coatings used in solar absorbers. Metals used in early solar absorbers, such as copper and iron underwent natural oxidation, and thus reach a desirable absorption. However, as the oxidation processes occur naturally, they are difficult to control, which results in a change in the thermal emittance of the material and eventual degradation of the layer with a subsequent change of the energy efficiency of the absorber.

For low temperature heat collection, or not for year round use, the black paint is in practice a cost-effective option. Selective paint on polished aluminium or galvanic steel reaches a solar absorption of  $\alpha=0.85\sim0.91$  and a thermal emittance of  $\varepsilon=0.23\sim0.40$ . However, at high temperatures, the paint is likely to melt or burn off the surface, releasing volatile organic compounds to the environment. This type of coating is not widespread in the European market.

Electroplated coatings are widely used in the solar absorber industry. These coatings are applied to the absorber plate metal in a wet process. Black Chrome is plated from chromic acid bath solutions. The black chrome and black nickel coating exhibit solar absorption and thermal emittance values ranging from  $\alpha=0.92\sim0.98$  and  $\varepsilon=0.06\sim0.25$ , respectively, and is thermally stable at 325°C on nickel-coated copper and stainless steel substrates. There are also anodised electroplating coloured selective absorption coatings on a aluminium surface ( $\alpha=0.85\sim0.91$ ,  $\varepsilon=0.23\sim0.40$ ). Coatings on stainless steel have also a potential market in solar thermal applications where glazing is not required and in higher temperature systems including parabolic concentrators. Another type of wet process is the sol-gel technique used for Black Majic coatings.

Vacuum deposition processes are a newer technology for flat plate absorbers with an increasing share of producers. Physical vapour deposition (PVD) depicts a group of processes where at least one of the reactants, not in a gas phase, is evaporated in a vacuum chamber by either heat, sputtering (atomisation), or arc-evaporation. The processes are used also for evacuated collectors and as the receivers in high temperature solar thermal systems. A process of vacuum based selective coating of black chrome uses a high power electron beam gun to evaporate the chromium oxide, which gets deposited on pre-heated copper substrate. PVD coatings an aluminium exhibits solar absorption and thermal emittance values ranging from  $\alpha=0.92\sim0.96$  and  $\varepsilon=0.03\sim0.07$ , respectively (Alanod (2002)).

Further information about these processes can be found in different subchapters of chapter 8.6 and in the literature (Duffie & Beckmann (1991); Haefer (1987)).

## 8.4 Application of Selective Coatings

The selective coatings investigated for this dataset are used for solar absorbers. In the last years there was a shift in the market share of products sold. The total market for selective coatings in the EU is estimated to be 1.2 Mio. m<sup>2</sup> per year (not including vacuum tube absorbers and painted absorbers). The market share for black chrome coatings is decreasing in the last years. This is mainly due to the lower prices for PVD coatings. Today about 35% of the coatings on the market are made by black chrome coatings.<sup>20</sup> And about 20% of solar absorbers sold in Germany are electroplated.<sup>21</sup>

## 8.5 System Characterisation

Different types of selective coatings for solar absorbers are investigated here as far as data or at least some information on environmental aspects were available. There are other selective coating processes for solar absorbers which could not be investigated in this study due to the lack of data. A short description of these coating processes is provided in the next chapter. Readers interested in details are referred to the literature.

## 8.6 Life Cycle Inventories for Selective Coatings

Existing life cycle assessments for solar absorbers showed that the impact of the selective coating as such and differences between different processes are not very important for the total environmental

<sup>20</sup> Personal communication, Werner Ledderboge, Gibo-Solar, and Kai Bohn, ChromeCoat A/S, 7.2002.

<sup>21</sup> Personal communication V. Handke, IZT, Berlin, 5.2002.

impacts caused by the absorber (Althaus (1999); Streicher et al. (2002)). More important is the choice and the amount of the substrate materials like copper and aluminium used for the construction and the overall energy efficiency of the solar absorber. Nevertheless there is a big discussion about the environmental impacts of different coating technologies. Main concerns of the discussion were i.e. the energy use for production and the emissions of chrome and acids with the effluents. Thus a detailed investigation of data for the coatings might help to better understand the influence of the coating for the total environmental impacts due to the production of a solar absorber.

Most of the data for the life cycle inventories have been derived from questionnaires sent to different manufacturers. The report (IPPC (2002)) does not contain many helpful information specific enough for the processes investigated here.

The unit process raw data are investigated gate-to-gate and refer to the coating of one m<sup>2</sup> metal sheet. The metal sheet itself (substrate) is not included in the inventory. Production processes outside of Europe are assumed with an European electricity mix. For production processes with only single manufacturers the country specific electricity mix is assumed. Standard transport distances have been used for the delivery of materials if not stated otherwise.

### **8.6.1 Vacuum Deposition Processes**

#### **Sputter coating on copper sheet substrates with chromium and tin oxide**

The life cycle inventory for metal coatings on copper made by a sputtering process is based on data provided by a German manufacturer<sup>22</sup> for its production in 2001. An environmental report of this manufacturer for 2000 (Interpane (2000)) was available for comparison. The production process has been improved further on. In 2002 the waste heat of the new production plant is used to replace fuel oil for room heating. The company and the environmental report is certified according to EU eco-audit EMAS and DIN/ISO 14001. Tab. 8.2 shows the unit process raw data and the data quality indicators for this coating technology. The product is sold under the brand name Sunselect. Data for 2001 are shown for the total annual production and per m<sup>2</sup>. Data for the previous year are only shown per m<sup>2</sup>.

The data provided by Interpane could directly be used for the life cycle inventory. The total production in 2001 was 440000 m<sup>2</sup>. The copper sheet has a thickness of 0,2 mm and a weight of ca. 1,8 kg/m<sup>2</sup>. Interpane is applying a sputtering process (cathode evaporation method) for the coating of absorbers. Argon, nitrogen and oxygen are used as process gasses for the process. The target materials chromium and tin are used with an efficiency of 50%. Water is mainly used for cooling and thus it does not have to be treated afterwards. Materials are mainly bought from German producers. The amount of copper sheet substrate coated is not included in the inventory for the coating process, but the amount of copper wastes is included as a demand. These relative clean wastes are recycled.

The emissions stated in the environmental report are not considered here because they are derived from literature values for diesel and electricity use. Instead the burning of the fuels is considered with ecoinvent background data. The transport distances for recycled wastes are not included in the inventory. The used copper sheets (substrate) are not cleaned or pre-treated in a special way by the supplier. The quality is the same as the ones used by other coating manufacturers.

(Frischknecht et al. (1996)) has also estimated data for this process without specifying the origin. Lampert (n.d.) gives some information for a black nickel coating made by magnetron sputtering in Sweden which is also shown in Tab. 8.2.

---

### PVD coatings on copper sheet substrates with titanium-nitrite-oxide

The life cycle inventory for metal coatings on copper made by a physical vapour deposition (PVD) process is based on information found in the internet for a German producer (Tinox (2002)). Tab. 8.3 shows the unit process raw data and data quality indicators for this coating process. Copper is coated by TINOX in a process with a titanium-nitrite-oxide ( $\text{TiN}_x$ ,  $\text{TiO}_y$  and a small amount of  $\text{TiC}$ ) layer in a vacuum chamber. Fig. 8.1 shows a schematic production process in which 200m<sup>2</sup> copper sheets substrate are coated per batch. An electron beam gun is used for the evaporation process. The layer is coated with  $\text{SiO}_2$  for protection and antireflection (Lampert (n.d.)).

Quantitative data for the use of nitrogen and oxygen in the process were not available. The same figures as for the sputtering process are used. An eventually necessary pre-treatment of the copper sheet outside of the factory and losses of coated material are not included in the data.

**Fig. 8.1** TINOX batch reactive evaporation process. An electron beam gun is installed in a chamber. Oxygen and nitrogen are steadily added to the process that is controlled online (Tinox (2002))

### PVD coatings on aluminium sheet substrates

(Alanod (2002)) uses a selective PVD coating for aluminium sheet substrate. During the hot rolling process an additional unwanted oxide film forms, which is incorporated into the rolled surface during the cold rolling process, thereby leading to irregularities in the surface. In order to avoid these irregularities to the texture or the chemical composition of the aluminium, Alanod degreases the surface and then it is electro-chemically brightened. Here the top layer of the strip is removed, so that the pure metal now forms the strip surface. As a further result of this process, micro roughness will be evened out.

This pre-treated aluminium surface is then oxidised in an acid anodising bath with the help of electrical energy. During this process a very dense but very thin oxide film develops, the so-called barrier layer. The thickness of this layer depends on the level of the direct voltage employed during the anodising process. The barrier layer, which consists mainly from aluminium oxide, is a good electrical insulator.

The multi-layer selective coating is deposited on the anodised aluminium substrate. Three optically active layers are applied continuously in an "air-to-air" thin film process.

The last production step incorporates the sealing of the pores, whose diameter is in the range of 15 nm. To enable this, the strip is passed through a bath of almost boiling water, which is responsible for the formation of so-called boehmite crystals thereby closing the pores. The oxide layer on the top are optimised for a good solar absorption ( $\alpha$ ). After the final drying process, the anodised surface is mechanically as well as chemically protected. The anodised aluminium coil is now ready for use.<sup>23</sup>

Quantitative data for energy and resource uses and emissions of this process were not available.

## 8.6.2 Wet Processes

### Aluminium oxide-based layer pigmented with colloidal nickel on aluminium sheet substrates

Selective coatings with an aluminium oxide-based layer pigmented with colloidal nickel are used by one company in Germany. The coatings are made in Slovakia by anodisation in phosphoric acid followed by electrolysis in a nickel pigmentsing bath. The inventory is based on previous published data (Frischknecht et al. (1996)). These data have been provided by the manufacturer in 1993. The production process has been improved in the meantime, but new data were not available (Thermosolar (2002)).<sup>24</sup> Tab. 8.4 shows the unit process raw data and the data quality indicators for this selective coating process. Losses of coated materials are not included in the inventory.

**Tab. 8.4 Unit process raw data and data quality indicators for aluminium oxide-based layer pigmented with colloidal nickel.**

### Black chrome coatings on copper sheet substrates

First a nickel layer is deposited on the metal sheet for the black chrome coating of copper substrates. Then chrome in the oxidized form is used for the second layer. The company (mti (2002)) uses chromium metal and chromium oxide (Cr<sub>2</sub>O<sub>3</sub>) for the selective black chrome. This type of chrome (Cr<sup>3+</sup>) is less poisonous than the well known Cr<sup>6+</sup>.

Black chrome coatings with nickel underlay are produced by ChromeCoat A/S in DK. Several years of field experience showed that this type of coating is a durable selective surface for solar absorbers. The chemical solution is used mainly in a closed loop. Waste products are not directly emitted to the envi-

<sup>24</sup> Personal communication with Mr. Novak, Thermosolar AG, SK, 7.2002.

ronment. Rinsing water is treated by ion exchangers and returned back to the line. The polluted water from the regeneration of the ion exchangers passes a vacuum evaporator that separates water from metals, acids, etc.. The remaining waste is treated in a chemical treatment plant. Some data for this process have been provided in a questionnaire (Tab. 8.6), but this does not include the exact composition of the wastes.<sup>25</sup>

Data for the continuous process of black chrome coatings at MTI, US were available in a product brochure and from a questionnaire.<sup>26</sup> MTI Solar electrodeposits black chromium on nickel plated copper in a continuous plating process. This coating is marketed under the trade name KROSOL. The major process stages are:

1. Alkaline cleaning of copper to remove any oils on the surface and wash
2. Neutralizing with the acid to remove any oxidation and wash
3. Plating nickel on copper and wash
4. Plating black chrome on the nickel plated copper and wash
5. Wash and dry

The company MTI uses about 2.3kWh of electricity per m<sup>2</sup> of coated substrate including all pre-processes like cleaning. A major environmental concern for this process was the waste water from galvanic process. About 50% of the production costs at MTI are necessary for the treatment process for the effluents (Remmers (1998)). Tab. 8.6 shows the quantitative data for air emissions and the use of acids for this factory. Tab. 8.5 shows the concentration of water pollutants in the effluents from the MTI black chrome coating process. The bold figures have been used to assess the environmental impacts due to the treatment of these effluents (Doka (2003)). One square metre of coated copper sheet has a weight of 1.225kg. MTI has coated 8 Mio. m<sup>2</sup> in 30 years of production.

**Tab. 8.5 Concentration of water pollutants in the effluents from the MTI black chrome coating process**

| Water emissions        | Unit | Amount to public treatment plant |
|------------------------|------|----------------------------------|

| Lead                   | mg/l | <0.1 ( <b>0.05</b> )             |
| Zinc                   | mg/l | <b>0.21</b>                      |

Streicher (2002) investigated an energy use of 12.4kWh/m<sup>2</sup> for the producer Gibo-Solar, but this production plant has been closed.<sup>20</sup> The electricity use due to the chrome coating process has been estimated by Hofstetter *et al.* (1992) with 0.6kWh/m<sup>2</sup>. This value is not reliable because it was estimated based on laboratory experiments for normal black chrome processes made in the 1980's.

<sup>25</sup> Information provided in marketing leaflets and in a questionnaire by ChromeCoat, Kai Bohn, 7.2002.

<sup>26</sup> Personal communication with Dr. Kidambi Raghunathan, IPTE, Inc., US, 9.2002 and MTI Solar Selective Absorber Strip in Rolls and Modular Assemblies, MTI Materials Technology Inc., US.

The inventory for black chrome coatings on copper is included in the database calculated as an average for the information provided by different producers. Tab. 8.6 shows the unit process raw data for the coating process. The inventory is calculated with an European electricity mix. Losses of coated materials are not included in the inventory. Also transports from the US to Europe are so far not included in the inventory.

**Tab. 8.6 Unit process raw data and data quality indicators for selective coatings made by black chrome coating of copper coils. Inventory data from different production plants**

### Black chrome coatings on stainless steel sheet substrates

Live cycle inventory data were available for the deposition of black chrome on stainless steel in a galvanic batch process (Energie Solaire (2002)).<sup>27</sup> The main process stages used for the process at this Swiss production plant are:

- 1: Cleaning with electrolytic wash bath at ambient temperature (20°C)
- 2: Activation
- 3: Black chrome coating at ambient temperature (20°C)
- 4: Recuperation baths
- 5: Reduction bath

The detailed inventory for black chrome coating on stainless steel with the above mentioned process stages is included in the database. Tab. 8.7 shows the unit process raw data for the black chrome coating process. Rinsing water is recycled through a water treatment plant. There are no process specific air and water emissions. A part of the used water is evaporated in the process. Effluents with a chrome (III) content of 1.35% are recycled. Losses of coated materials are not included in the inventory. In tests this type of coating resists without any alteration to humidity, UV, high temperature – up to 530° – as well as acid rain and salted mist.

<sup>27</sup> Data and information provided in personal communication by Energie Solaire, CH.

### Black Majic coating on copper sheet substrates

Thermafin Manufacturing<sup>28</sup> in the USA uses a single-phase nanocrystalline technology for solar selective coatings in a sol-gel based wet process (Alternate Energy Technologies (2002)). The brand name for this process is “Black Majic”. The following list contains a description of the process stages used for the process:

1. obtain top-grade copper with microfinish
2. pre-clean copper prior to coating
3. activate copper surface with nickel
4. coat with Black Majic, these are crystals raised on the surface with a tin-nickel alloy plating solution
5. cure final product with a protective glass layer

Tab. 8.8 shows the properties of the tin-nickel plating solution. The alloy contains about 65% tin and 35% nickel. The amount of chemicals has been roughly estimated with the concentrations shown in the table and 50% of the amount of water used for the process.

\*Total fluorine should be at least as high as total tin:  $\text{Sn(II)} + \text{Sn(IV)}$ ; see text.

The crystals grow in a tin-nickel alloy plating solution. Hydrogen fluoride gas is used in the process. Alcohol is used as a solvent during the Black Majic coating (Remmers (1998)). The coating is fully encapsulated with a permanent protective glass layer made out of silica oxide. Some data for this process were available from a questionnaire. Tab. 8.9 shows the unit process raw data and data quality indicators for the Black Majic coating process. The electricity use has been assessed roughly by the company. The European mix is used instead of the mix for US, which has not been investigated for the background data. No information was available about process specific air and water emissions. Water emissions are estimated to be half of the amount of chemicals used for the process. Losses of coated materials are not included in the inventory.

**Tab. 8.9 Unit process raw data and data quality indicators for selective coatings made by Black Majic coating of copper.**

### 8.6.3 Coating Plant

The unit process raw data for the manufacturing plant in Tab. 8.10 have been assessed with data provided by different producers. Production data are rounded in the table due to secrecy reasons. The data for the coating plant have been normalized for a production capacity of 100000m<sup>2</sup>/a. The life time of the plant is estimated to be 30 years. The share of different production activities at (Interpane (2000)) for the total land use has been confirmed in a personal communication. The averaged inventory for the infrastructure is used for all coating processes. Data for necessary machinery were not available.

**Tab. 8.10 Unit process raw data and data quality indicators for selective coatings manufacturing plant.**

## 8.7 Data Quality Considerations

The simplified approach with a pedigree matrix has been used for calculating most of the standard deviation. Information for the aluminium oxide-based layer pigmented with colloidal nickel has been

provided by a manufacturer some years ago and is thus out of date. The inventory for the sputtering process is based on an externally verified environmental report with figures for all known energy uses and major emissions. Data for the PVD process are only a rough estimation with known data gaps for the use of materials. Data for the black chrome coatings on stainless steel and copper are reliable based on unverified information directly provided by the manufacturer. The data quality of the Black Majic coating process on copper is not very reliable. Only few data were available. Thus the unit process data have been derived by using some assumptions.

It has to be noted that the system boundaries for the investigation of different processes differ as the losses of coated materials, additional energy uses e.g. for cars, etc. are not included for all coating processes in the same depth. Thus a direct comparison of coating processes with these inventories is not possible. Also transports from the coating plant to the final customer, which might be important, have not been included in the assessment.

The overall data quality is sufficient for the aim of this section, the provision of background data for the life cycle inventory of solar absorbers. The results per square metre are not meant to be used for a direct comparison of coated absorbers. For that purpose the inclusion of all data for the absorber and the consideration of product properties is necessary (especially solar absorbance and thermal emittance, further materials, life time, etc.).

## 8.8 Cumulative Results and Interpretation

Tab. 8.11 shows selected LCI results and the cumulative energy demand for selective coatings on metal sheets. Instead of comparing different products, we just show minimum, maximum and mean values for the products investigated here. There might be quite large differences among the different coatings. But there is no one possibility that is the worst or the best in all aspects. Thus a very detailed comparison would be necessary.

**Tab. 8.11 Minimum, maximum and mean LCI results and the cumulative energy demand for selective coatings on metal sheets**

The following Fig. 8.2 shows the share of the selective coating in comparison to other components of the solar system (Jungbluth (2003)). It is quite clear that the impacts from the coating can be neglected in comparison to the production of the collector itself (especially the metal sheet), other components of the system (hot water storage) and in comparison to the operation of the system. Thus the discussion for the environmental improvement of solar collector systems should rather focus on the selective coating, but more on the amount and type of other bulk materials used.

**Fig. 8.2** Share of selective coating in comparison to other aspects for a flat plate collector with a black chrome coating (Jungbluth (2003))

## 8.9 Conclusions

The inventory of metal coating processes can be considered as a basis for the assessment of this process in connection with the production of solar absorbers. A direct comparison of different selective coatings based on these data is not advisable. Some environmental aspects could not be quantified for some processes. System boundaries differ for the different processes investigated. A comparison makes only sense for the amount of heat delivered by different solar absorbers including the production and dismantling of these appliances and not for the coating process alone. Thus the product properties (e.g. absorption and emittance, life time, further materials, etc.) of the solar collector have to be taken into account if a comparison for solar absorbers with different coatings is made based on the data investigated here.

We thank Frank Schröer, Felder GmbH Löttechnik, Markus Stutz, Motorola and Otmar Deubzer for information provided in personal communication.

### Abstract

This chapter contains the life cycle inventory information about the production of lead-free soft solders. The inventory is meant to be used as a background dataset for technical processes using soft solder. The product investigated is Sn97Cu3 that is made from tin (97%) and copper (3%). It is lead-free. The investigation is based on data provided by a producer and information from literature. Figures for the energy use and for wastes have been reported for a production plant. The use of other materials and process emissions to air have been reported in literature. General assumptions are used for transport distances. Furthermore data for the production plant were available. Energy uses of different soldering processes are discussed. But, due to the large variations possible a generic inventory has not been elaborated.

### 9.1 Introduction

This chapter contains the life cycle inventory information about the production and application of lead-free soft solders. The inventory is meant to be used as a background dataset for technical processes using soft solder. The lead-free product investigated is Sn97Cu3 that is made from tin (97%) and copper (3%). It is used i.e. for soldering of copper plates for the production of solar collectors.

### 9.2 Reserves and resources of product

Solders can be produced from a wide range of different metals. Important ingredients are tin, lead, copper, silver, cadmium, zinc and aluminium. Other metals and materials used in small proportions are i.e. phosphorus, arsenic, bismuth and iron (DIN (1997)).

### 9.3 Characterisation and use of soft solder

Relevant solders are mainly alloys of tin and lead with small amounts of other metals. They are used for a wide variety of engineering joining and repairing tasks, ranging from plumbing uses to the mass production of radiators/heat exchangers and electronic printed wiring boards (HMIP (1994)). In the context of this study soft solders used for the construction of solar absorbers are the main interest. One product that can be used for this application is Sn97Cu3 that is made from tin (97%) and copper (3%).<sup>29</sup> It does not contain lead.

### 9.4 System characterisation

The inventory is split up into the two stages of solder production and use during soldering. Data for solder production in Switzerland could not be found. Thus an European production scenario is assumed. The soldering itself is described in this report. Quantitative data from different case studies are

---

<sup>29</sup> Personal communication and information provided by Frank Schröer, Felder GmbH Löttechnik.

shown. But the soldering could not be investigated as a generic inventory due to the large variation of possible processes.

#### **9.4.1 Production of solder**

Her Majesty's Inspectorate of Pollution a regulatory board in Great Britain (HMIP (1994)) provides a description for the production process of solders:

*An important production route begins with the recovery and refining of scrap tin and lead materials. The process and its releases are outlined on the upper part of block flow diagram (Fig. 9.1); raw materials are any suitable scrap tin or lead bearing items, alloys and drosses. Frequently dross recovery services are provided to end users by the solder manufacturer.*

*Metallic scrap and highly metallic drosses are melted in kettles which are indirectly heated by oil, gas or electricity. Material with high dross or flux content is melted in sloping hearth reverberatory furnaces or rotary furnaces. These are directly heated using oil or gas. At the temperatures involved, organic type fluxes are vaporised or burnt off and appropriate gas treatment is necessary. During melting, oxide and residual fluxes float to the surface of the metal and are removed by drossing into drums or special containers using rakes, perforated ladles or, on large installations, machines.*

*The molten alloy is best refined, if necessary, by pyrometallurgical techniques although electrolytic refining is an effective alternative. In pyrometallurgical refining, the temperature is first lowered to precipitate high melting point impurities present in some quantity, such as iron and copper, which collect on the surface and are removed. Additions of chemicals at specific temperatures are then used to remove the remaining impurities. For example, sulphur is added to remove residual copper as the sulphide and ammonium chloride to eliminate zinc as zinc chloride. These form drosses which are sold for recovery of the metal. Sodium carbonate is added at the conclusion of the drossing to take up any excess chemicals.*

*Electrolytic refining uses anodes of crude solder and thin sheets of refined solder as the cathodes in a cell in which the electrolyte of hydrofluorosilicic acid or hydrofluoroboric acid is circulated. Tin and lead are deposited on the cathode whilst the impurities remain on the anode as a slime. Periodically the cathodes are removed, washed with water and melted. The impurity slime is brushed from the anode, washed and filtered. All metallic process waste is normally sold for recovery of the metal. Refined solder is cast into master alloy ingots by pumping or pouring into moulds followed by an appropriate air or water cooling method.*

*Solders are manufactured to national, international and company standard specifications. There is an end user driven move to lead-free or low lead alloys where this is technically acceptable, e.g. in gas plumbing uses. The annual usage ratio of bought-in to recovered materials varies markedly between different producers from over 90% to under 50%.*

Fig. 9.1 Typical flow sheet for solder manufacturing (HMIP (1994))

### 9.4.2 Soldering

For the use of solders the solder itself and the materials to be fixed have to be heated to a temperature higher than the melting point of the solder. The source of heat depends on the type of application.

## 9.5 Life cycle inventories

A review of existing studies for the life cycle of solder products shows that the production of metals and the use of solder are the most important stages in the life cycle. The direct energy use for the production of the solder is not so important. Fig. 9.2 shows an investigation of different types of solders used in the production of printed wiring boards (PWB) (Hamano et al. (2001)).

**Fig. 9.2** The difference of total energy consumption of PWB. Use of 400kg solder in one reflow line (Hamano et al. (2001))

The life cycle inventory is investigated for the production of lead-free solders. The soldering itself could not be investigated with quantitative data because it depends on the type of process used which might vary considerable between different producers and for different products.

### 9.5.1 Production of lead-free soft solder

The life cycle inventory for the production of soft solder (Sn97Cu3) is based on the information provided by a manufacturer in Germany (see footnote 29) and some additional information from literature. These basic information are shown on the right side of Tab. 7.1.

Seegerberg (1995) has estimated the electricity use for the production of solder (solder mixing, casting and atomisation) to be 0.325kWh/kg of solder. Oelichmann (1997) has used this inventory and extended it for the use of some more auxiliary materials. He calculated an electricity use of about 0.5kWh/kg. Data for a new process for the atomisation of solder powders are provided by a company (Atomising Systems Ltd (2002)). This process uses about 0.17kWh electricity per kg metal. Other estimates give the energy use for solder production to be 2 and 5 MJ/kg.<sup>30</sup> The Felder GmbH produces about 2000t of this type of solder (Sn97Cu3) per year (which makes only a small part (1%) of its total production). About 500MWh (0.25kWh/kg) of electricity and 1666GJ (0.83MJ/kg) of natural gas are used for the production of this specific product in one year. These figures are used in the inventory.

The new process of (Atomising Systems Ltd (2002)) uses about 1.4l of inert gas per kg metal. HMIP (1994) shows data for maximum releases to the air during the production of solders (Tab. 9.1). Data for air emissions related to a specific amount of product were not available. Process specific emissions have been estimated with the maximum releases (Tab. 9.1) and the flow rate of inert gas (0.62m<sup>3</sup> nitrogen per kg or 0.8kg/kg, investigated by Oelichmann (1997)). The emissions of ammonia, hydrogen chloride, NMVOC, and the main metals copper and tin are calculated with the flow rate of nitrogen for the specific product investigated here.

| Chlorides (as HCl)                                                                 | 30                                             |
| Ammonia                                                                            | 15                                             |
| Volatile organic compounds (measured as total carbon excluding particulate matter) | 50                                             |

Tab. 7.1 shows all unit process raw data for the production of soft solders. The metal use has been calculated from the content in the product and a loss as metal ashes of 1%. The metal content of the solder is 90%, the rest is flux. Transport distances have been used according to the general guidelines. The producer provided also data for the use of water for cooling. Metal ashes (10g/kg) and packages (0.01m<sup>3</sup>/kg) which are recycled according to the information of a producer are not considered as disposed wastes for the inventory. Data for other wastes have been reported by the producer.

### 9.5.2 Solder production plant

The inventory for the land use of a solder production plant has been elaborated according to the general guidelines. Data for the land use of one production plant (3300m<sup>2</sup> of buildings and a total area of 4500m<sup>2</sup>) have been reported by the producer. The production of 2000t is equal to 1% share of the total production. Thus the total production of this plant is estimated to be 200'000t/a. Tab. 7.1 shows the unit process raw data for a generic solder production plant with a production capacity of 100000 tonnes per year and a life time of 50 years.

### 9.5.3 Soldering

Seegerberg (1995) has estimated the electricity use for the use of solder in screen printing to be 5.58kWh/kg of solder. Hamano et al. (2001) have investigated the use of solder during printing wiring board (PWB) production (Tab. 9.2). They reported a much higher specific energy use between 739 and 918MJ/kg which makes this process to the most important one in the life cycle of solder products. Oelichmann (1997) reported an electricity use of about 200kWh per kg of used solder for the reflow soldering process.

**Tab. 9.2 The energy data of one reflow line Hamano et al. (2001). Type of energy use not specified**

| MJ/kg                  | Soldering (reflow) |
|------------------------|--------------------|
| SnPb                   | 835                |
| SnAgCu (existing)      | 918                |
| SnAgCu (energy saving) | 739                |
| SnZn                   | 835                |

Soft solder is used for the construction of solar collectors. Here a copper sheet and copper tubes are fixed by solder. The two components can be heated up together in an oven, by an electric heater or they can be soldered by using heat from propane or hydrogen combustion. The energy use might vary considerable between different companies due to different technologies and the standard of energy saving technologies.<sup>29</sup>

Fig. 9.3 shows the manufacturing of a solar collector with copper pipes (Soltop (2002)).

**Fig. 9.3 Soldering of solar collectors**

Generic unit process raw data for the use of soft solders could not be investigated. The energy use, the type of energy and the equipment used show great variations, which makes it impossible to provide a generic inventory. Instead it is recommended to investigate the energy use for melting separately for each process using soft solders with plant specific data.

Tab. 9.3 Unit process raw data and data quality indicators for the production and use of soft solders and the solder production plant. References are presented in the text

## 9.6 Data quality considerations

Tab. 7.1 shows the data quality indicators for the inventory of production and use of soft solders. The simplified approach with a pedigree matrix has been used for calculating the standard deviation. Large uncertainties exist for data on emissions and for the transport distances of materials.

## 9.7 Conclusions

The inventory for the production of soft solders can be considered as a reliable basis for the assessment of this material in connection with technical applications. It is not meant to be used for the comparison of different solders. For that, detailed information about product properties and type of application would be necessary.

## Abbreviations

DIN (1997) is a valuable source for the description of abbreviations in the context of soldering materials.

## Appendices: EcoSpold meta information

|                    | 492 GeneralComment             | The inventory is meant to be used as a background dataset for technical processes using soft solder. The lead-free product investigated is Sn97Cu3 that is made from tin (97%) and copper (3%). The investigation is based on data provided by a producer and information from literature. | Inventory for a production plant with an annual capacity of 100'000t and a life time of 50a.           |

## 10 Powder coating

Author: Hans.Jörg Althaus, EMPA, Dübendorf  
Review: Roland Hischier, EMPA, St. Gallen

### 10.1 Definition and fundamentals of powder coating

In powder coating the coating material is applied to the workpiece in the form of dry thermoplastic or thermosetting powder. The powder particles are heated and melt to form a sealed film. The thermoplastic powders melt and fuse on heating whereas the thermosetting powders forms chemical cross-links. Two main application processes are used: electrostatic spraying and fluidized-bed coating. (Meyer (1997))

The cleaning of the workpiece before coating can either be done mechanically (e.g. steam / high pressure water blasting) or chemically. Chemical degreasing includes solvent degreasing, alkaline degreasing, pickling, phosphating and chromating. The last two methods are mainly applied to enhance corrosion resistance either of the workpiece between degreasing and coating or after coating.

#### 10.1.1 Environmental issues of powder coating

The cleaning of the workpiece is likely to be the most important environmental issue of powder coating. Depending on the method used this step emits VOC to air or metals and hydrocarbons to water.

According to Meyer (1997), powder coating is the coating method that produces the least environmental pollution because the occurrence of paint slurry is avoided, the separation of dust – air mixtures is simple, and the coating powders are solvent-free and generally cure by polyaddition.

Dust emissions from powder coating are generally below 5 mg coating powder per cubic meter of exhaust air. Emissions from the driers (basically organics) are generally also extremely low.

Coating powders without hazardous components (e.g., lead pigments) do generally not have toxic or fibrogenic effects. The fraction of respirable dust that can penetrate the lungs is  $\ll 10\%$  (w/w).

### 10.2 Coating powder

Thermosetting coating powders are produced exclusively by the extruder process. Most commonly used are powders on the basis of epoxy-polyester (ca. 60%), polyester-trisglycidyl isocyanurate (ca. 20%), epoxy (ca. 15%) and polyester-polyurethane (ca. 5%). (Percentage of European production in 1998 (Meyer (1997))).

Inorganic pigments (e.g., titanium dioxide, iron oxides, and chromium oxides) are best suited for coating powders because of their thermal stability, their inert behaviour towards other constituents of the powder, their mechanical stability to withstand the extrusion process and because they don't affect the binder viscosity too much. Lead pigments are sometimes still used for exterior-grade powder coatings. In Europe the use of cadmium pigments is declining.

A 1:1 mixture of epoxy and polyester resin is chosen for modelling the powder inecoinvent. Powders of this composition are mainly used for exterior architectural applications. The pigment inventoried is  $\text{TiO}_2$ . Thus the coating powder inecoinvent stands for a white powder for applications e.g. in the building sector.

The background information to the process "coating powder, at plant" is given in Tab. 10.1, flows are shown in Fig. 10.1.

## Data quality

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed.

| General Comment to reference function | A 1:1 mixture of epoxy and polyester resin is assumed. Powders of this composition are mainly used for exterior architectural applications. The pigment inventoried is TiO <sub>2</sub> . Other pigments (and thus other colours) could have very different ecoprofiles. Since many different powders are available on the market, the representation of a specific powder can be poor. |

### 10.3 Powder coating of steel

The 2 mm thick steel sheet is cleaned by alkaline degreasing and pickling. The data for these two processes from zinc coating of steel are used. The sheet is coated with a layer of 80 µm and cured at 220 °C. The heat energy consumption for the curing is calculated using the energy consumption reported by a Swiss producer<sup>31</sup>. Since the data in this source is given for steel and aluminium together, the curing temperature and the thermal capacity of the steel and aluminium sheet are used to estimate the share of the energy demand for each of these materials.

The dataset includes neither the steel sheet nor its transport to the coating plant.

The background information to the process "powder coating, steel" is given in Tab. 10.2, flows are shown in Fig. 10.2.

#### Data quality

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed.

| powder coating, steel, part 2 | m            | Waste water                           | Treated waste water. Total emissions are estimated based on the degreasing / pickling process in the zinc coating process of steel. Infrastructure for waste water treatment plant is comprised in the infrastructure module. Value for energy use is comprised in the range of uncertainty of inventoried overall energy. |                             |                            |                |          |                                                                              | 6.54E-03   | m3   | IPPC 2001                |      |          |                                                           |

Fig. 10.2 Flows for "powder coating, steel" and their representation in the ecoinvent database (cont.)

## 10.4 Powder coating of aluminium

The 2 mm thick aluminium sheet is cleaned by alkaline degreasing and chromatising. Some of the data for these processes from powder coating of steel sheets are used to account for the Cr and hydrocarbon emissions to water. Other emissions are neglected because for them the pickling of steel seemed not suitable as proxy. The sheet is coated with a layer of 80 µm and cured at 220 °C. The heat energy consumption for the curing is calculated using the energy consumption reported by a Swiss producer<sup>32</sup>. Since the data in this source is given for steel and aluminium together, the curing temperature and the thermal capacity of the steel and aluminium sheet are used to estimate the share of the energy demand for each of these materials.

The dataset includes neither the aluminium sheet nor its transport to the coating plant.

The background information to the process "powder coating, aluminium" is given in Tab. 10.3, flows are shown in Fig. 10.3.

### Data quality

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed. The data are based on rough estimations and of poor overall quality.

| General Comment to reference function | The powder inventoried is mainly used in exterior architectural applications. The coating thickness is 80 µm. The heat consumption is calculated for a sheet of 2 mm thickness. |

| powder coating, aluminium sheet, part 2 | m            | Waste water                           | Treated waste water. Total emissions are estimated based on the degreasing / pickling process in the zinc coating process of steel. Infrastructure for waste water treatment plant is comprised in the infrastructure module. Value for energy use is comprised in the range of uncertainty of inventoried overall energy. Chromium and organic emissions taken from cleaning of steel sheet as proxy. |                             |                              |                |          |                                                                              | 6.54E-03   | m3   | IPPC 2001               |      |          |                                                           |

# 11 Anodising of aluminium

Author: Hans.Jörg Althaus, EMPA, Dübendorf  
Review: Roland Hischier, EMPA, St. Gallen

## 11.1 Definition and fundamentals of anodising

This chapter is mainly based on Lyle & Granger (1997).

Anodising is an electro-chemical process converting the aluminium surface to aluminium oxide. Two principal types of anodised coatings are recognized: barrier and porous.

The barrier coating is formed by aluminium ions from the base metal combined with the oxygen of water in the electrolyte. If the oxide is appreciably soluble in the electrolyte a relatively thick, porous oxide layer can develop.

The most common electrolytes for conventional thick porous anodised coatings are sulphuric acid solutions. These coatings are decorative or protective and range in thickness from 4 to 30 µm. Chromic acid anodised coatings are thinner and less abrasion resistant than the sulphuric acid coatings, but they are more flexible and more resistant to deformation and heating without crazing. Oxalic acid anodised coatings are somewhat harder than the sulphuric acid coatings.

Anodic coatings are coloured by certain alloying elements. Aluminium – silicon alloys provide durable grey coatings widely used as exterior architectural finishes. Chromium and copper in solid solution yield light gold finishes, and manganese imparts tan to brown shades. Porous anodic coatings can be impregnated with organic and inorganic dyes and pigments during anodising by incorporating the dyes and pigments in the electrolyte or during a post-anodising treatment.

Many anodic coatings are porous and subsequently are sealed to improve resistance to staining, resistance to corrosion, and durability of the colours. Sealing is accomplished by immersion in hot water.

### 11.1.1 Environmental issues of anodising

The use of solvents and acids for the cleaning, pickling and anodising of the aluminium is likely to be the most important environmental issue of anodising. These steps emit VOC to air and / or metals and hydrocarbons to water.

## 11.2 Anodising in ecoinvent

The anodising of aluminium involves the following steps:

- Mechanical pre-treatment (sanding, brushing, polishing, abrasive blasting) is made to eliminate defects and irregularities. This step is not always done and therefore inventoried only for 50% of the anodised sheets.
- Chemical pre-treatment (degreasing, pickling) is made to degrease and deoxidise the surface and to eliminate heavy metals from the surface.
- Electrolytic oxidation builds up the oxide layer.
- Post-treatment (sealing) hardens and consolidates the oxide layer.

Process data used in ecoinvent is based on Richter et al. (1996), who report data from 1995 for two anodising plants in Switzerland. Data correspond to an oxide layer thickness of 20 µm.

The background information to the process "anodising, aluminium sheet" is given in Tab. 11.1, flows are shown in Fig. 11.1.

### Data quality

The uncertainty is estimated by completing the pedigree matrix, according to (Frischknecht et al. (2003)). A lognormal distribution is assumed.

# 1 Introduction

Antimony and its sulphide have been known and used for several thousand years. It occurs natively and is found in over 100 mineral species. The predominant ore mineral of Antimony is its sulphide, stibnite ( $\text{Sb}_2\text{S}_3$ ). Antimony is mainly mined from complex sulfidic ores with iron, copper, lead, mercury or silver.

## 2 Reserves and Resources of Antimony

Antimony, like copper, lead and zinc, is a markedly chalcophilic (sulphur loving) element. Its estimated abundance in the Earth's crust is 0.2 to 0.5 ppm. Antimony occurs natively and is found in over 100 mineral species. The predominant ore mineral of Antimony is its sulphide, stibnite ( $\text{Sb}_2\text{S}_3$ ). Antimony is mainly mined from complex sulfidic ores with iron, copper, lead, mercury or silver (USGS 2007). China produces more than 80% of the world antimony, mainly from stibnite. The largest mine in China is Xikuangshan mine in Hunan Province.

Secondary antimony stems mainly from the recycling of lead acid batteries in which antimony is used as an alloying element (ca 2% w/w). In the mid 1990s, about 30% of the European and 22% of the United States antimony production originated from secondary antimony from this source (Ullmann 2006). Antimony is almost exclusively recycled at lead smelters and consequently used in lead-antimony alloys, mainly lead acid batteries.

The world-wide secondary antimony production share today is considerably lower than it was ten years ago, mainly for three reasons:

1. the antimony content in lead acid batteries decreased in the last decades due to the introduction of low-maintenance batteries in the 1970s. Thus the main source for secondary material decreased and is still decreasing.
2. the world antimony production increased from ca. 90'000 t/a in the mid 1990s to over 130'000 t/a in 2005 and 2006.
3. Europe and the U.S. already had a high consumption of lead acid batteries before 1970 when the main producers of antimony (China, Russia & Bolivia) still had a very low car (and therefore lead acid battery) density. Thus, countries with high potential for secondary production like Europe and the U.S. are insignificant contributors to the global antimony supply (less than 3%). The secondary production share in significant contributing countries like China, Russia or Bolivia is low. Thus, world average secondary production share is a lot lower than the European or the U.S. share.

As a consequence of 1) and 2), recycled antimony dropped from 22% in the mid 1990s to only 15% of the total U.S. market supply in 1999 (USGS 2007). Today, the share of recycled antimony on total global production is estimated to be less than 5%.

### 3 Characterisation of the material

The element antimony (Sb, 7440-36-0) is a blue-white metalloid. In its elemental form it is a silvery white, brittle, fusible, crystalline solid that exhibits poor electrical and heat conductivity properties and vaporizes at low temperatures. A metalloid, antimony resembles a metal in its appearance and in many of its physical properties, but does not chemically react as a metal. It is also attacked by oxidizing acids and halogens. Antimony and some of its alloys expand on cooling (negative thermal expansion). Some physical properties are listed in Tab. 3.1.

Tab. 3.1 Some physical properties of antimony.

| Physical properties of antimony <sup>1</sup>                   |         |
|----------------------------------------------------------------|---------|
| Melting point °C                                               | 630.9   |
| Latent heat of fusion, kJ/mol                                  | 19.87   |
| Boiling point °C                                               | 1587    |
| Latent heat of vaporisation, kJ/mol                            | 77.14   |
| Vapour pressure, Pa @ 630.9 °C                                 | 2.49E-9 |
| Density, g/cm <sup>3</sup> @ 26 °C                             | 6.684   |
| Mean specific heat, J g <sup>-1</sup> K <sup>-1</sup> 0–100 °C | 0.21    |

Antimony is comparable in its toxicological behaviour to arsenic and bismuth. Poisoning with antimony and its compounds can result from acute and chronic exposure, especially from exposure to airborne particles in the workplace.

Commercial grades of antimony trioxide (the principal commercial form of processed antimony) contain 99.2 to 99.8 % trioxide with iron, lead and arsenic as main impurities. Commercial antimony metal is usually at least 99% antimony with no more than 0.3% arsenic impurity. The largest amount on the market is Chinese No. 2 grade, which has minimum 99.65% antimony. Antimony metal prepared for semiconductor use in electronics is 99.999 plus pure. (USGS 2007)

Antimony sulphide ore is marketed in at least three forms: “lump sulphide ore”, “clean sulphide concentrate” and “Chinese concentrate” (USGS 2007). In the 1990s, much of the high grade metal and the trioxide was produced in the consuming countries from imported concentrates, metal or crude oxides. However, a trend from concentrate towards metal and oxide imports was observed during the last decades (USGS 2007). The U.S. geological survey estimates the U.S. imports of ores and crude oxides in 1999 to approximately 7’700 tons. On the other hand, 39’000 tons of refined metal and oxides were imported in the same year, more than 20’000 tons of which from China. Since the end of the 1990s, China closed down several antimony production sites, impede illegal (or informal) operations and set up a policy of no more selling ore concentrates but refined products. Thus, it can be expected that today, most of the antimony trioxide and metal production takes place in China.

## 4 Use / Application of the Material

Flame retardants were estimated to account for 60% of global antimony consumption in 2000. The remaining 40% were equally shared between Alloys, mainly lead alloys primarily used in lead acid batteries, and other uses. The principal commercial form of processed antimony is the trioxide, which is mainly used in flame retardants for plastics (USGS 2007). Antimony compounds in the form of Oxides, Sulfides, Sodium Antimonate, and Antimony Trichloride are also used in the making of ceramic enamels, glass, paints, and pottery. Also, Antimony Sulfide is one of the ingredients of safety matches.

Antimony is increasingly being used in the semiconductor industry in the production of diodes, infrared detectors, and Hall-Effect devices. As an alloy, this metalloid greatly increases Lead's hardness and mechanical strength. The most important use of metallic antimony is as a hardener in lead for storage batteries. Uses include:

- Batteries
- Antifriction Alloys
- Type Metal
- Small Arms and Tracer Ammunition
- Cable Sheathing
- Matches
- Medicines
- Plumbing
- Soldering - Some "Lead-Free" Solders Contain 5% Sb
- Main and Big-End Bearings in Internal Combustion Engines (as Alloy)
- Used in the past to treat Schistosomiasis; today Praziquantel is universally used
- Used in Linotype Printing Machines

## 5 System Characterisation

This chapter describes the mining of sulphidic antimony deposits and the related extraction of antimony.

Mining processes are similar for all sulfidic ores. Open pit mining and underground mining are both applied for antimony. No information was found on the share of the two types of mining. The ores are concentrated to up to 60% Sb content by froth flotation. Low grade ores (1.5 to 25% Sb) are roasted to produce antimony oxide. Medium grade ores are smelted in blast furnaces to produce crude metal. High grade ores (>45% Sb) are liquitated, i.e. heated in reducing atmosphere to melt the sulphide and separate it from the gangue. The blast furnace process is the most important process for the extraction of antimony.

Since not enough information was found on antimony ore composition, mining and beneficiation, the mining and beneficiation of molybdenite from coupled production with copper is used as proxy. This seems reasonable since molybdenum occurs in about the same concentration as antimony together with copper and since the beneficiation processes are basically the same.

The metallurgical processes in the Antimony production are comparable to those in lead and zinc production. Since no quantitative data was available, the production of Antimony is approximated with the smelting process of lead.

Tab. 5.1 gives the meta information to the processes while Fig. 5.1 and Fig. 5.2 show the LCI flow-sheets for the datasets.

Tab. 5.1 Meta information for the mining of antimony bearing ore and the smelting of antimony.

Fig. 5.2 Flows for "antimony, at refinery" in the ecoinvent database

### 5.1.1 Data Quality Considerations

Not much is known from public sources about quantitative process measures. Therefore the data has been established based on theoretical reasoning and rough assumptions, extrapolating the data from molybdenum mining and lead refining. This dataset approximates metallic antimony and is not to be used when antimony is used as flame retardant (as an oxide) or when it is a substantial part of the system modelled.
